CATALYSIS and its Industrial Applications. By E. JOBLING, M.C., A.R.C.Sc., B.Sc., A.I.C. Second Edition. Philadelphia: P. Blakiston's Son & Co., 1920.

The average medical man has heard of the use of catalytic agents and perhaps is familiar with one or two methods in which they are used, the Kjeldahl method for instance, but he has no idea of the tremendous importance which these "inorganic enzymes" have in industrial chemistry. Jobling's little book reviews briefly many of the methods in which catalytic agents play an important part and indicates the explanations which have been given concerning the manner of their action. The book is perhaps not one which will help the reader to be a better physician but it is intensely interesting, especially to those who are familiar with chemistry. The second edition has been thoroughly revised during the past year.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 2, 1920.

THE THIRD VICE-PRESIDENT, DR. RUFUS I. COLE, IN THE CHAIR.

THE program of the evening was arranged in cooperation with the Section on Surgery.

The Intravenous Injection of Large Doses of Sodium Citrate—A New Method for the Control of Bleeding.—Dr. HAROLD NEUHOF, in collaboration with Dr. Samuel Hirschfeld, presented this contribution. They stated that when the citrate method of blood transfusion was introduced, in 1915, the question that at once arose was whether the intravenous introduction of sodium citrate, recognized as an anticoagulant, would not result in a suspension of coagulation in the recipient's blood. It was soon established conclusively that this did not occur; in fact, a transient shortening of the coagulation time in the recipient, with a subsequent return to the previous level, was found to follow the transfusion of citrated blood. The writers had undertaken experiments in an effort to seek an explanation of this paradoxical action. Their first step was to determine the toxic and lethal dosage of sodium citrate. The results of these experiments showed that, contrary to the observations of Lewisohn and others, there was no fixed toxic dose of sodium citrate per kilogram of body weight, but that toxicity depended to a remarkable degree upon the rate of intravenous introduction of the citrate solution. In general, it could be stated that the toxic dose of sodium citrate was much larger than that given by Lewisohn and others, the minimum being 6 grams for a dog weighing 10 pounds, when given over a period of 20 minutes. Their main purpose in administering sodium citrate in lethal quantities was to learn its effect on coagulation time under such circumstances. They had found that the effect of slow lethal doses given to dogs manifested itself by a suspension of coagulability of the blood. The writers then described their experiments dealing with the intravenous introduction of "normal" nontoxic quantities of sodium citrate. They found that within fifteen minutes of the introduction of the citrate solution the coagulation time dropped from a normal of five to eight minutes to two minutes, and even less. This was followed by a profound change in the color of the blood withdrawn from the vein, the appearance being that of almost pure arterial blood. In these experiments the effect of sodium citrate on bleeding was at least as marked as that on coagulation; the bleeding time became greatly shortened. This was observed in a large number of instances in which large veins were divided and the rapid cessation of hemorrhage was noted. During the war Dr. Neuhoof had gained the impression that there was a greater tendency for the cessation of hemorrhage from fresh gunshot wounds following citrate blood transfusion than after the transfusion by the paraffined flask method as employed in the British service. Upon examining Lewisohn's papers on the results of citrate transfusion this impression was strengthened. In short, they believed it was the sodium citrate and not the blood that played the important rôle in controlling hemorrhage. Hemorrhage in the case of blood disease was not referred to. Experimental work confirmed this belief. Few and incomplete observations had been reported on the effect of sodium citrate administered intravenously in the human being. Weil reported the administration of sodium citrate in one case, an adult, in whom 5 grams of 20 per cent. solution were injected. The coagulation time was halved; no other data were given. In a case of hemophilia, described by Ottenberg, a minute dose (0.6 gram) was followed by a marked drop of coagulation time. Forty-eight hours later a prolongation of the coagulation time was found. Kinsella and Brown reported an attempt to control hemorrhagic manifestations on five influenza patients, and had noted a marked effect. Finally they had learned within the past few days that Weil had attempted to control bleeding in three patients by the intravenous administration of one gram doses of sodium

citrate; the results were not published. They had found no reports in the literature of any study of the possible effects of so large doses of sodium citrate on bleeding, so clinical observations were begun on the service of Dr. Lillenthal at Mount Sinai Hospital, and were being continued at the present time. They had found that the optimum dose was 6 to 8 grams in 30 per cent. dilutions for adults, and 1 to 3 grams for children. The largest quantity they had given was 14 grams to an adult and there had been a number of instances in which 10 and 12 grams had been administered. No evidences of toxicity were observed in any of the seventy-five injections of large doses of sodium citrate up to and including the dose of 14 grams. Hence the assertion of Lewisohn and others that 5 grams was the maximum human dose could not be accepted. The only untoward manifestations observed were minor complaints during or immediately following injection. It was their practice to stop the injection at the first expression of discomfort and to continue the introduction of the fluid only after that particular symptom had disappeared. Some patients described a salty taste, some mentioned trembling of the lips or tingling sensation in the extremities; others complained of dizziness, or nausea, or sense of oppression, or occasionally a feeling of tightness across the chest or abdomen. No untoward after-effects had been noted and no toxic effects on the kidneys. The effects of large doses of sodium citrate administered intravenously in the human being corresponded closely to those observed in their animal experiments. The typical curve in respect to coagulation time was as follows: Five minutes after the injection a coagulation time of 10 minutes dropped to 7 minutes; 10 minutes later it reached 5 minutes; in one-half hour after the injection the coagulation time was between 2 and 3 minutes. The peak was reached some 40 minutes after the injection and was sustained in the neighborhood of a two-minute coagulation time for an additional hour. It then returned to normal, but this was much more gradual than the rapid drop after the injection. In 6 hours the coagulation time reached 5 minutes. In some instances the normal was reached in 24 hours, in others not until 48 hours after the administration of the drug. No subsequent changes in coagulation time had been seen in observations taken up to six days following the injection. Of notable interest was the fact that the coagulation time was shortened by citrate injections to a similarly striking degree in patients in whom it was pathologically prolonged, especially in jaundice. They had noted drops in coagulation time from sixteen minutes to two minutes following the injection. There were some cases in which a more prolonged effect was desired than that obtained from a single dose of citrate. They had attempted to sustain the shortened coagulation time by repeating the dose after twenty-four and thirty-six hours. As a result the drop in coagulation time had been maintained in some instances for several days, to return to normal in about a week; in other cases the second dose had little or no additional effect. All types of bleeding, medical as well as surgical, that had been encountered had been controlled by large doses of sodium citrate administered intravenously. Large doses of sodium citrate had been successfully used to prevent hemorrhage in cases in which bleeding was anticipated at operation. This method offered a large sphere for the control of bleeding, was simple of application, and had proven both nontoxic and safe.

Dr. GEORGE BAEHR said that some years ago he had had the opportunity to assist Dr. Lewisohn in some of his experiments preliminary to the utilization of sodium citrate for blood transfusion in human beings. They had immediately observed that the intravenous injection of sodium citrate in animals was followed by a prompt and appreciable reduction in the coagulation time of the blood. This was so marked that in some dogs $\frac{1}{2}$ to 1 gram of sodium citrate shortened the coagulation time from six or seven minutes to two and even to one minute. In some instances this effect was so pronounced that the blood coagulated almost instantaneously upon being drawn into a test tube from the carotid. This at once suggested the question whether this was due to the transfused blood or to the sodium

citrate, and they found that the reduction in the coagulation time was due to the citrate and not to the transfused blood. Dr. Weil had independently reached the same conclusion and had published the observation. Recently Dr. Rosenthal and himself had investigated the subject from a different standpoint. They had endeavored to ascertain the mechanism which was responsible for this remarkable shortening of the coagulation time after the introduction of sodium citrate. The possibility of a change in the calcium balance first suggested itself in view of the fact that sodium citrate delayed coagulation *in vitro*, but it was found that the calcium was not responsible for the change *in vivo*. After the intravenous injection of sodium citrate, the calcium content of the blood showed no change even when the coagulation time was markedly shortened. They then made observations in reference to the fibrinogen in the blood of the patient after the administration of sodium citrate, and they found that the quantity of fibrinogen remained absolutely normal. They next carried out observations in reference to the antithrombin content of the blood according to the method of Howell, and found that there was no change in the antithrombin of the blood. In other words, the shortened coagulation time after the administration of sodium citrate was not due to calcium, to fibrinogen, or to a diminution in antithrombin. They found, however, that regularly in all their experiments there was a marked increase in the prothrombin factors in the blood. There were several prothrombin factors in the blood, and it was difficult to determine which one was responsible for the shortened coagulation time. They believed they had now ascertained which factor was responsible, but their experiments were not yet sufficiently numerous, and at the present time they are not yet prepared to make any more definite statement than that the shortening of the coagulation time of the blood following the intravenous administration of sodium citrate is due to a proportionate increase in prothrombin. Dr. Baehr said that although observations had previously been made by Weil, Lewisohn, himself and others that the intravenous injection of sodium citrate shortened the coagulation time of the blood, he felt that credit should be given to Dr. Neuhof for having introduced this procedure therapeutically on a large scale and for having shown that it had a wide practical application. All credit in that respect was accruing to him.

Dr. RICHARD LEWISOHN said there were a few points about which he would like to speak, and the first was with reference to the toxicity of sodium citrate. It seemed to him remarkable that when he undertook his investigations in 1914 nothing was known with reference to the toxicity of sodium citrate; there was nothing in the textbooks as to how large doses of the drug could be given with safety. In the experiments executed in collaboration with Dr. George Baehr, they had found that 15 c.c. in a 10 per cent. solution was fatal to a dog weighing 11 pounds. He had stated in his first paper on this subject that 15 grams would be fatal to a human being weighing 110 pounds. In a person of average weight, 150 to 160 pounds, 22 grams of sodium citrate should be considered a fatal dose. There had always been some doubt expressed whether those conclusions should stand which were taken from animal experimentation and transferred to human beings. Carter, in 1915, expressed the opinion that not 15 but 30 grams should be considered the fatal dose for human beings, and the same opinion was advanced by Chaton in 1916. It was certainly of the greatest interest to all of us that Dr. Neuhof had shown by clinical observations in a large series of cases that sodium citrate was not nearly as toxic as it was supposed to be. That fact was of great interest, but he hoped the conclusion would not be reached that there was no toxicity associated with the use of sodium citrate. From the standpoint of blood transfusion in applying the citrate method, the observations of Dr. Neuhof were certainly of great interest. They showed two important points: (1) The chills which occurred after transfusion in about 20 per cent. of the cases, even when small doses of sodium citrate (not more than 2½ to 3 grams) were used, were not due to the sodium citrate as such. (2) There were no contraindications to the use of the citrate method

either in hemorrhage or in the so-called blood diseases, in which it would prevent further bleeding. Dr. Neuhof's conclusions were based upon two facts. The first was that he had shown the comparative atoxicity of sodium citrate when injected slowly, and second, he had shown that sodium citrate could be used to stop bleeding. When a great deal of blood had been lost this procedure might not serve all clinical purposes. There were cases in which we might wish not only to stop bleeding, but to replace blood that had been lost and in those cases transfusion would still be of a great deal of value. When a donor was not at hand the fact that sodium citrate, in the dosage stated by Dr. Neuhof, would control hemorrhage, would certainly be of great value.

Dr. HOWARD LILIENTHAL said he had been very much interested in the investigations carried on in connection with the use of sodium citrate in blood transfusion. He believed he was the first surgeon who had had opportunity to make use of sodium citrate transfusion in a human being. This was a case supposed to be carcinoma of the stomach. There had been a loss of weight and a few other symptoms suggestive of carcinoma, but no definite diagnosis had been made and he wished to make sure by excising a small node in the left supraclavicular space (Virchow's gland). Dr. Lewisohn made the transfusion by the citrate method and he removed the node with the patient under local anesthesia. He noticed and remarked at the time that there was less bleeding than one would have naturally expected during an operation of that type. If sodium citrate prevented coagulation *in vitro* it would seem that it should have the same effect in the human body. It would be interesting to know just why it did not have this effect in the human body. It seemed probable at present that oxygenation had something to do with it. He had been interested in the work of Dr. Weil and others who were working out the idea of the use of sodium citrate to prevent hemorrhage, and when Dr. Neuhof asked to try it out he was glad to give him the opportunity and was particularly pleased with the happy results. They had had a case of polycythemia, a woman who had had teeth drawn and was bleeding profusely. The bleeding sockets were packed and then sodium citrate was used. The first injection did not yield results, but the second dose did. In another case, a laryngeal case, in which Dr. Neuhof assisted at the operation, it was not necessary to tie more than four blood vessels after giving the sodium citrate, though the operation was one which ordinarily would have been very bloody, as the larynx was split from the thyroid notch to the intraclavicular space, and the pharynx was opened by another incision across the thyroid space so that it lay wide open. In this case there was little bleeding, and not more than four arteries had to be tied. He had expected no such an effect as this from the sodium citrate injection. Hemorrhage of all kinds was unquestionably influenced by sodium citrate, though it would not take the place of ligatures or surgery. It would act, however, as a first aid, and as Dr. Lewisohn said the hemostatic effect was one more important reason for the use of the citrate blood transfusion rather than any other method. Dr. Baehr had gone into the action of sodium citrate in the blood, and stated that the coagulating substances were increased in quantity by the citrate. It seemed that we had here another instance of the action of nature in trying to correct something that was doing harm and here overcorrecting the noxious tendency. For instance, in the case of irritation of a part of the peritoneum nature immediately used the omentum to seal off that region. In the action of sodium citrate in hemorrhage we had a substance introduced into the blood which ordinarily increased the coagulation time and nature in making an attempt to correct it went to the extreme and overcorrected by the formation of substances which increased the coagulating power of the blood.

Dr. E. LIRMAN said that it might be interesting in connection with what Dr. Lilienthal had said to find out whether sodium chloride given intravenously had any effect on coagulation time. Van de Velde had, as was well known, recommended the intravenous use of sodium chloride for hemoptysis and had claimed to have had results. As Dr. Baehr had stated, Dr. Richard

Weil had made the first observations on the effect of sodium citrate on the coagulation time of the blood. These studies were made at the time that Dr. Lewishohn was studying the value of citrate transfusion. Dr. Weil had found that citrate of soda would cut the coagulation time in half within one-half to one hour after the intravenous injection had been given, and that it would return to normal within twenty-four hours. Dr. Weil had suggested that sodium citrate doses in aqueous solution be used intravenously and he had begun studies in Dr. Libman's ward when the war broke out. It was rather curious to note that at that time there were some sharp reactions following the use of the citrate solution, and that Dr. Neuhof had witnessed no reactions. The question might be raised whether the drug used at the time was pure. Dr. Libman said that the studies made by Dr. Neuhof and Dr. Hirschfelder were the first real studies on the practical value of the use of citrate of soda for stopping hemorrhages. It seemed to him that the observations made by Dr. Neuhof and Dr. Hirschfelder on the prevention of hemorrhage by the use of sodium citrate before operation were particularly valuable. It had always been considered advisable to use transfusions as a preoperative method for preventing hemorrhage, but even in cases where it was most needed it had seldom been used. The sodium citrate method was so simple that more attention would be paid to preventing hemorrhage at the time of operation or afterwards, than had ever been done before.

Dr. NEUHOF, in closing the discussion, said that in reference to Dr. Baehr's remarks he was merely theorizing, whereas Drs. Baehr and Rosenthal were working on the question of the changes in the blood elements after sodium citrate injections. He did not question their provisional report that prothrombin was the element that was affected but both Dr. Hirschfeld and he had been so impressed by the change in the color of the blood after citrate that they believed oxidation must also play some rôle in the effect produced. Dr. Neuhof said he was pleased to hear Dr. Lewishohn express his views about the toxicity of sodium citrate. He said he and his coworker had observed, as shown in their paper, that sodium citrate could be toxic and unquestionably lethal in animals. That was why they had reported their experiments showing that a dose that might be toxic if administered rapidly was without toxicity if injected slowly. They could only repeat with the greatest emphasis that slow introduction was the only method that should be used. Another point brought out by their investigations was that the sodium citrate method of blood transfusion appeared more desirable than and not merely as desirable as any other method in many cases of hemorrhage. They had as yet had no experience with sodium citrate in hemorrhage in blood diseases except in the one case of polycythemia they reported, and whether that observation would be found to hold good in other instances he could not say. It seemed evident that in the single case of hemophilia reported by Dr. Ottenberg the coagulation time of the blood was profoundly affected by the very small dose of sodium citrate given to that patient. The later prolongation of the coagulation time in that case might have been due to the fact that the dose was so small. Dr. Neuhof wished to make one minor correction in the remarks of Dr. Lillenthal. In the case of polycythemia the bleeding from the gums was controlled for six hours following the injection of sodium citrate, bleeding then recurred to stop permanently after the second dose of the drug. In reference to Dr. Libman's remarks on the use of normal salt solution to induce changes in coagulation, Dr. Neuhof stated that they had tried such solutions without noting any effect on coagulation time. Dr. Neuhof expressed himself as pleased that Dr. Libman had again mentioned the fact that Dr. Weil was the first to give a large dose of sodium citrate (five grams) and to note that the coagulation time of the blood was thereby shortened. He also had indicated this fact in the body of his paper.

The Economic Value of Preventive Surgery in Industry.—Dr. JOHN C. A. GERSTER read this paper, in which he stated that during his past two years' experience as a surgeon to a hospital for the re-education of the industrially crippled, and as surgical advisor to a

casualty insurance company, the author has been repeatedly impressed with the amount of unnecessary and readily preventable disability encountered in the course of his daily work. In striking contrast to the policy of life insurance companies which made it a point to keep abreast with scientific medical progress affecting their interests, the casualty insurance companies as a body had gone on the way unheeding the common basic principles of accepted surgical practice as applied to their own field. They had failed to appoint expert buyers for the commodity, surgical treatment. In a recent series of 220 healed simple fractures of the extremities with marked disability, referred to an industrial rehabilitation hospital for possible improvement, the vast majority of cases showed readily preventable deformities. In other words, these deformities represented a vast sum paid out for preventable disability.

Dr. Gerster then outlined briefly the kind of service that a casualty company had a right to expect from the hospitals, and suggested that should local hospitals not prove amenable to constructive criticism it might be considered whether industry itself could not undertake increasing industrial human salvage by the organization, equipment, and management of large hospital centers with related dressing stations throughout the country; the personnel of these centers to include leaders in medicine and surgery. The chief object of a surgical department of a casualty company was to make sure that a man was receiving proper treatment from the hour of his injury until he was cured. This implied: (1) Report by telephone of accidents, ascertaining exact nature of injury, authorizing transportation, diagnostic measures, form of treatment, and consultation with specialists. (2) Maintenance of a daily follow-up system, especially with reference to a reminder file regarding motion at the earliest possible moment conducive with safety. Failure to start early motion at the right time was the greatest factor causing loss of function in fractures and hand infections. (3) Supervision of medical bills from outlying districts. The outside surgeon must render a concise statement of the original injury, the treatment and course of cure, together with the final result. The company paying him was entitled to a knowledge of these facts. (4) Analysis of results. Cases of preventable disability to be subject of weekly and fortnightly conferences with claims and executive departments to ascertain means for correction of underlying causes. Surgical information should be disseminated for the guidance of claim departments, generalizing procedures in given conditions, as (a) Every fracture should be regarded as an emergency and reduced as soon as possible. (b) Compound fractures might often be converted into simple fractures if proper surgical treatment was applied within six to eight hours from the time of injury. It was recommended that Thomas splints be used in transporting patients suffering from fractures of the thigh and leg from plant to hospital. (c) So-called contusions of the hip should be x-rayed. Patients had been known to limp even a mile or two after fracture. (d) Infection of the hand could often be prevented by prompt application of tincture of iodine. By such a simple means as this one large corporation reduced the number of finger infections 80 per cent. (e) In wounds of the fingers the palm or near the wrist divided tendons could be diagnosed by requesting the patient to open and close the hand. Failure of complete motion indicated the necessity for immediate surgical attention. Information might be supplied to employees regarding certain common injuries and infections, and what they meant, what surgery held out to them—what they might expect; what risks they ran from self-treatment or neglect.

These pertinent matters, he said, could be printed in bulletin form to be posted at conspicuous points in factories and offices. The education of employers should include not only what surgical neglect would cost them, but also what surgical care would save them. A few typical examples would drive home the argument that nurses could not replace doctors in treating minor injuries. The loss of a few fingers every year would more than offset this saving in salaries.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Held November 24, 1920.

THE PRESIDENT, DR. HERMAN B. ALLYN, IN THE CHAIR.

Newer Aspects of the Clinical Study of Tumors.—Dr. JAMES M. EWING of New York read this paper, in which he said that the results of the past 20 years in experimental cancer research had been disappointing in their relation to the practical side of the cancer problem. They had had very little influence on the death rate from cancer, and, while the real progress of knowledge might not be measured by practical results, it was a sobering thought that the conquest of cancer was not to be achieved by the recent scientific contributions of the research laboratory. The importance of these contributions should not be underrated. It had been shown that there was no such thing as immunity against cancer, although a certain resistance to tumor growth had been observed under many conditions. No essential difference between tumor tissues and normal tissues had been demonstrated as regards the chemical composition, the ferment activities, or the mode of growth. So far as experimental cancer research was concerned, we were apparently not to have a new cure for cancer, nor any new and easy method of diagnosis, nor any revelation of specific etiology. We were still required to recognize the disease by the crudest of methods, by looking at it with our eyes and through the microscope; and most us still had to treat it by the equally crude method of cutting or burning it out. Mammary cancer, one of the most familiar forms of malignant tumor, presented wider variations in natural history than almost any other. It occurred as a fulminant febrile disease, fatal in a few weeks or months, or as a prolonged and relatively harmless affection lasting many years. It was therefore of no significance to determine the duration of mammary cancer as a whole or to state the general result of operation. The disease had to be subdivided. Unless mammary cancer existed in a form and size recognizable by the trained naked eye it was doubtful if it existed in a clinical sense. Age and state of nutrition of the patient were determining factors in the prognosis of mammary cancer. In florid young women under 30 years a mammary cancer had a very unfavorable prognosis, and many thoughtful surgeons refused to operate on such subjects. After 70 fewer operations would be performed if the surgeon would consult the tables showing the expectation of life at those periods. The author's experience with surgical material convinced him that too many women suffered radical operation for conditions that proved not to be cancer. This state of affairs was the result of the general assumption that any lump in the breast was to be regarded as cancer until it was proven otherwise, and that it was unsafe to make an incision into a localized cancer. But the majority of lumps in the breast were not cancer. The majority of those that were could be recognized by competent clinical and physical examination, and he knew of no evidence, clinical or experimental, that justified the belief that a clean incision into a breast cancer for diagnosis disseminated the disease. Certainly it did less harm than the squeezing and kneading of the scores of examinations that most mammary cancers received before they reached the operating room. The first thing to do with a lump in the breast was to determine its nature. He ventured to express the hope that in the not distant future the surgery of mammary cancer might be greatly restricted from its present scope and, without daring to make any predictions, he trusted it might eventually be entirely discarded and replaced by physical therapy. During the past 10 years a complete transformation had occurred in the clinical and therapeutic setting of uterine cancer due to the introduction of radium therapy. The majority of cervical cancers appeared to fall in the basal celled group, so that in about 80 per cent. of uninterrupted fatal cases the disease was limited to the pelvis and death resulted from occlusion of the ureters. Since the term sarcoma was applied to very numerous and very diverse groups of malignant tumors, it was obvious that the simple designation sarcoma was no diagnosis. One had to be quite specific in the recognition of the sarcomatous diseases, and this accuracy was generally best attained by stating the exact

cells or tissues of origin or by the use of some definitive clinical term which was free from obscurity. The absolute necessity of distinguishing sharply between different forms of sarcoma was well illustrated by those occurring in the limbs and bones. Not always, but generally, all these tumors appearing in the surgical clinic were masked in one grand class of "malignancy in bone," and most of them were consigned to but one treatment, amputation. Yet one could hardly find in the entire range of oncology more diverse diseases in clinical study, gross anatomy, histological structure, and natural history. They included wholly benign processes tending to spontaneous healing after many years or the most malignant of neoplasms fatal in a few weeks. If any important impression was to be made in our time upon the debility and mortality from malignant tumors, it was everywhere agreed that earlier diagnosis and earlier treatment must be secured. This service could be rendered only by learned and skilful clinicians. All along the line there was need of more cordial reliance upon the simple direct method of clinical study at the bedside and the morphological study of tissues in the laboratory. In the field of tumors it appeared that we had not yet begun to exhaust the resources of these methods.

When and Why Surgery Offers the Best Chance for Cure.—Dr. JOSEPH COLT BLOODGOOD of Baltimore delivered this address, in which he said that surgery of malignant disease was an attempt at complete removal with the knife or the cautery. Since the discovery of the x-ray and radium we had observations that these radioactive agencies inhibited or destroyed the vitality of the malignant cell. Inasmuch as complete removal with the knife or cautery had cured cancer, it was of importance to ascertain what method of treatment offered the patient the best chances of a permanent cure. We were educating the public to the fact that delay in treatment was dangerous, but we must also remember that in the early operable stage of cancer delay in the selection of the best treatment was just as dangerous. Unfortunately there was difference of opinion as to the best first treatment in malignant disease of different types, originating in different localities in the various tissues and organs. At the present time we had for comparison largely the results of surgical treatment with the knife and cautery. These records in many clinics needed careful restudy and revision. With these data brought up to date we should be able to give the profession the exact results, and upon these data only should the decision rest as to the first treatment. In the past and at present the percentage of cures of malignant disease had a large element of error due, first, to incorrect clinical and pathological diagnosis. Permanent cures of cancer were recorded as the result of different forms of treatment in which the local disease was not cancer, but some type of inflammatory or non-malignant process which had a tendency to spontaneous recovery.

Second, the clinical course and duration of malignant disease of different types in various tissues and organs varied with the different types and different individuals, and many cures were recorded when the disease was still present and running its natural slow and latent course. We needed to know the results of treatment in which these elements of error had been eliminated as far as possible for the practical question of what treatment to institute first. In the majority of localities inoperable cancer was due to delay due to ignorance. In the majority of instances, when inoperability could be established by the clinical picture and examination, and the pathological study revealed a process the malignancy of which was unquestioned, surgery offered no cure and other agencies could be tried without any danger from delay. It was in this group of operable cancers that the chief danger lay in the selection of the wrong first treatment. No one today should feel competent to decide which treatment should be instituted first unless that individual had a special knowledge of the pathological processes of the locality in which the disease had arisen. One might be a good operator and an expert technician with the x-ray and radium, and yet be without this essential equipment. Patients with possible cancer should receive the benefit of a thorough examination by one or more individuals trained in diagnosis.

Non-Surgical Methods of Treating Cancer.—Dr. HENRY K. PANCOAST of Philadelphia read this paper, in which he said that in the treatment of malignancy the object to be obtained was the eradication of all tumor cells either by extirpation or by some destructive process. The favorite procedures of the present day were surgery, exposure to the Roentgen rays, the use of radium, and the application of heat. Injections of Coley's fluid in sarcoma were well worthy of consideration. In the endeavor to obtain the best results one should never be so biased in his opinion as to follow solely that procedure in which he was best trained and equipped, with disregard for all others, but should select the method or combination of methods most likely to accomplish the result with greatest certainty in the least time with minimum danger to the patient's life and important structures, and in some parts of the body, as the face, with due regard to unnecessary sacrifice of normal tissue. In the treatment of cancer in some regions of the body, as the stomach and bowel, surgery was the only procedure offering practically any chance of success, but, to be effectual, it had to remove every cancer cell, because the supplementary use of Roentgen rays or radium offered very little hope when surgical removal failed. In other regions, as the uterine cervix, breast, and lower lip, the question of unusually rapid metastasis was of paramount importance, and surgery was the quickest method of extirpation. Here again, however, it had to eradicate every cell. Radiation and heat, usually in the form of electrothermic coagulation, were employed routinely in these regions in the so-called palliative treatment in inoperable cases, and the more successful they proved to be the more they encroached upon surgery in the borderline operable case. Only in case of the lower lip had anyone hazarded to place them on an equal footing with surgery, but, even in this instance, very important reservations had to be made in respect to technique before they should be in any way considered in this respect. In other localities, where early metastasis did not have to be so carefully considered, as other portions of the face and especially the eyelids, radiation and electrothermic methods usually offered better cosmetic results and were uniformly successful. In the mouth surgery was difficult as a rule, possibly excluding the tongue, and growths were so frequently found at an inoperable stage. Fortunately, in these cases, if not too extensive, radiation and electrothermic methods offered considerable hope of success. Probably no branch of medicine offered a greater field for haphazard work than did that which embraced the use of the destructive agents in cancer. They had come into extensive use before the profession at large could be educated in their proper application and principle. That they were extensively employed in an improper manner and without adequate training should be generally recognized. Exposure of body tissues to x-rays brought about definite and well recognized effects. Both the volume and penetration of the rays could be measured and controlled. The output of an x-ray tube was a bundle of waves varying somewhat in their powers of penetration just as did the various components of the light spectrum. For the effect on different depths of tissue definite degrees of penetration were required, and they were obtained by controlling penetration of the output and by filtering out waves of feeble and undesirable degrees of penetration. The exact effect upon cells was not known, but it was probable that the production of secondary radiation within the tissues played a part. Radium was one of the elements of high atomic weight which had an unstable atom and was undergoing at a constant rate a process of decay and giving rise to the phenomena of radial activity. The beta particle was thrown off with a velocity approaching that of light, and, for this reason, and also because of its small mass, it was highly penetrating, approximately a millimeter of lead or silver, half a millimeter of platinum, or three millimeters of aluminum being necessary to stop it. This was the actual therapeutic agent in the superficial use of radium and it might also be in the deep application. So far as had been determined at the present time the effects of radium and of x-rays upon the tissues were the same. The general effect upon the tissues following the prolonged application of radiation was, first, stimulation; longer exposure induced an inflammatory reac-

tion and still longer cell destruction. Therapeutic action depended upon the production of one of these reactions in the tissues. The effect upon healthy or apparently healthy cells was largely in the order of their specialization. In tumors susceptibility bore a certain relation to the approach of the cells to the embryonal type. Diseased cells with lowered vitality were more influenced than healthy cells. Certain lymphoid structures under abnormal conditions exhibited a remarkable susceptibility to radiation. The effect upon the smaller blood vessels and lymphatic vessels of prolonged radiation was an obliteration of the lumen through proliferation of the intima. This was a distinct advantage in the lymphatics, as it tended to check metastasis. The effect of radiation was to a certain extent cumulative, but one massive dose was more effectual than several smaller ones frequently repeated.

Dr. JOHN G. CLARK of Philadelphia said he felt as a member that he personally was very much indebted to Dr. Ewing for the splendid paper which he had presented. He had seen Dr. Ewing in his workshop, he had seen his splendid application of his scientific knowledge every day with his clinical confreres. What Dr. Bloodgood had done in the cancer propaganda and the good he had done was known to all. As he had pointed out to us this evening, a high percentage of cures could be obtained by surgical measures if the cases were taken in time. Dr. Pancoast had alluded to the use of radium in cancer of the cervix. Their series had now run well up to 200 cases. They started by taking what they considered inoperable cases. Because of the extremely good primary effects which they obtained in the inoperable cases, the number of operable cases became fewer and fewer. In other words, the case had to be distinctly operable at the present day before they undertook to treat it by surgical methods. He had seen frightfully inoperable cases freed from their distress and general symptoms for a time, and this alone was an argument in favor of the use of radium. In the group of inoperable cases in which treatment had been carried out four years or more ago, 18 per cent were alive. Because of the fact that radium could not affect the metastases it could cure only a limited number of cases. As Dr. Ewing had expressed it, this new phase of work would open up the question of the real etiology of cancer and perhaps through some of these avenues one might approach the subject in a clear way. We were all at the present time working empirically.

Dr. GEORGE E. PFAHLER of Philadelphia said that he had not been able to follow cases as long as had Dr. Bloodgood, but that he had had 75 cases of epithelioma of the lip, and he had not failed in a single one to get it well; he had had no metastases and the patients had remained well anywhere from six months to six years. Now what he did in these cases was to destroy by preference the disease locally by electric coagulation and then gave a thorough full dose over the chin, covering this whole area with the x-rays, and he then treated the submaxillary region on both sides, going the limit of skin toleration. The patient was seen once a month for two or three months and then at longer intervals for two or three years. The patient was treated two to six times after this destruction. He expected to cure all epitheliomas of the skin, even when they were large, by means of the x-rays or radium, without much local deformity. He preferred to use radium alone on the eyelid, because less contraction resulted. In cases of cancer of the cervix he believed we must learn to get as much radiation into the cancer tissue at once or within two weeks' time as possible. He thought if we treated with only a small amount of radiation that these embryonal cells gradually became adult cells, which developed resistance to radiation, and then we could not touch them without destroying surrounding tissue. Therefore early thorough radiation would help us to get all these patients well.

Dr. WILLIAM L. CLARK of Philadelphia said that his experience taught him that by combined methods better results could be obtained than by surgery alone; he referred to radium, x-ray, and the electrothermic methods. It had been his policy to treat these patients by a combination of x-rays and radium, but chiefly by radium. He had found it possible to insert the radium into hollow needles and to introduce these needles into various parts of the tumor. It had been his policy not to ex-

cise the glands, but to insert into them hollow needles containing radium. If the glands did not entirely disappear it was found that they had broken down in the center and that a fibrous capsule had formed, and no malignancy remained.

Dr. JOSEPH COLT BLOODGOOD said that he thought that there could be nothing more helpful to those who were using other treatment than to know the absolute results of surgery. When results of cures were based upon a careful pathological examination of tissue made by different pathologists, cures then were confined to malignant disease. When one removed a wart from the face, he did not include that in his cures of cancer; when one removed the breast, he did not include that. It was very easy to increase the number of cures by any treatment by inaccurate pathological examination. In fact, one could get many good pathologists to tell him that the lesion that had been removed was cancer. He believed that if a specimen had been submitted to more than one pathologist and there was a disagreement it was not cancer. He believed that many breasts were removed for lesions that surgeons of the past had never seen because they had disappeared before the surgeon had the opportunity to see them.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

MEDICAL COUNCIL OF CANADA.

October, 1919.

(Continued from page 210)

MEDICINE (INCLUDING THERAPEUTICS).

1. Give the symptoms of acute rheumatic fever. Indicate the commoner complications and contrast the clinical forms as seen in the child and in the adult.
2. Discuss the diagnosis of empyema as a complication of pneumonia. Definitely outline the treatment.
3. How may one differentiate cardiac murmurs: (a) organic, (b) functional (including extra cardiac)?
4. Discuss the signs and symptoms of influenza—affecting the respiratory system. Give the treatment of influenza pneumonia.
5. In a case of chronic nephritis with hypertension and arteriosclerosis, (a) discuss the treatment, (1) hygienic, (2) dietetic, (3) medicinal; (b) indicate briefly the possible complications in the respiratory and nervous systems.
6. Discuss the diagnosis of acute cerebrospinal meningitis, from the clinical and laboratory viewpoint. Outline the treatment.

SURGERY.

1. Describe the different fractures of the femur; symptoms, diagnosis, and treatment, apparatus and operations.
2. Pleural empyema, causes, symptoms, and treatment.
3. Give the pathology, clinical features, and the complications of stone in the common (bile) duct.
4. Acute dilatation of the stomach: (a) condition under which it may occur, (b) discuss the diagnosis fully, (c) give your treatment.
5. Extensive compound fracture of humerus, prognosis, and treatment.
6. Urethral stricture, classification, causes, and situation.

ANSWERS.

MEDICINE (INCLUDING THERAPEUTICS).

1. *Symptoms of acute rheumatic fever*:—"After a feeling of malaise, more or less soreness, and general stiffness, and very often after an attack of tonsillitis, the rheumatic pain begins in one of the larger joints: usually the knees, wrists, or ankles. The arthritis extends very rapidly to any of the medium-sized joints. At first the affected joints are red, hot, swollen, and intensely painful; later, the redness becomes less marked, and the joint may assume a dead-white appearance. Frequently the inflammation rapidly subsides in one joint, only to appear in another. The pulse is rapid, full, and soft. The temperature may be very high, rising even to 107° F.; indeed,

hyperpyrexia is not uncommon in this fever. In the majority of cases, however, it remains between 101° F. and 103°. It usually reaches its height in twenty-four hours, and is very irregular. *Marked sweating* of a peculiar sourish smell is a constant feature, and the various hair follicles and other cutaneous glands may become inflamed. *Anemia* may become pronounced. The urine is scanty, high-colored, and often loaded with urates. *Murmurs* either hemic or organic, may often be heard over the heart.

"*The more common complications are*:—Endocarditis, most frequent in youth, and affecting oftenest the mitral valve. It occurs in about half the cases. Pericarditis, less frequent. Myocarditis, which may be slight or profound. Pleurisy. Hyperpyrexia, often attended with delirium or coma. Certain skin eruptions, such as sudamina, miliaria, "petioles" or small red petechial spots around the ankles, and purpura. Pharyngitis and tonsillitis."—(Wheeler and Jack's *Handbook of Medicine*.)

Clinical peculiarities of acute articular rheumatism in children:—"The arthritic symptoms in children are in abeyance, while endocarditis and pericarditis are predominant, and may appear before the joint lesions are observed. Endocarditis follows the joint lesions twice as frequently in children as in adults. Stress is laid upon reduplication of the cardiac second sound, audible at the apex only, as an indication of the development of endocarditis. Rheumatic tonsillitis is common, and may precede, accompany, or follow attacks of rheumatism. Erythema is a frequent concomitant, and is often mistaken for scarlatina. The febrile movement is brief and hyperpyrexia less frequent than in the adult. The nervous features are more marked, notably chorea."—(Anders' *Practice of Medicine*.)

2. "*The symptoms of metapneumonic empyema* consist of fever, continuous with or coming on after that due to the pulmonary inflammation. Chills may occur, but generally do not, except at the onset of the fever, which often rises rapidly to a considerable degree. Sweats are of frequent occurrence, especially at night, but pain and dyspnea are rarely noted. Leucocytosis is generally found and is very suggestive, especially if it reappears after a postcritical absence. The physical signs are those of pleural effusion; and the exploring needle and the x-ray should be repeatedly used in doubtful cases, for when the exudate is encysted or between the lobes, a positive diagnosis may be impossible without their aid. The exudate of a pneumococcus empyema is odorless, thick, greenish yellow, and rich in cellular elements. Microscopically the leucocytes are mostly of the polymorphonuclear variety, mononuclears and endothelial cells being relatively few in number. Generally the pneumococcus is found; sometimes there is a mixed infection with pyogenic cocci, such cases being more severe in character, and accompanied by a higher mortality. Sometimes spontaneous absorption may occur but such an event should never be expected or awaited. Occasionally aspiration may bring about a cure, but generally resection of the ribs is necessary. If let alone the pus may rupture into neighboring structures such as the lung, bronchus, or pericardium."—(Osler and McCrae's *Modern Medicine*.)

Treatment of empyema: "Aspiration seldom cures, but may be undertaken where the dyspnea is great, and an anesthetic given afterwards for the excision of a piece of rib. Drainage is always necessary, and is best done by excising a portion of the fifth or sixth rib in the mid-axillary line. The patient should be allowed to come round quickly from the anesthetic, so that the coughing which occurs will expel the masses of coagulated lymph and help to expand the lung. A big drainage-tube is then inserted. Daily dressings are necessary, but irrigation of the cavity is seldom needed. If, because of delay in treatment the cavity does not soon close, Estlander's operation, or some modification, must be performed. The wound must be enlarged and a number of ribs exposed, and sufficient of them removed to convert the cavity into a pyramidal one, the base of which is the open wound. This is packed with gauze and allowed to heal from the bottom. If the operation has to be extensive, the flaps are allowed to fall back upon the granulating

surface of the lung, and in these cases marked scoliosis and weakness of that side of the chest follows."—(*Aids to Surgery*).

3. *Organic murmurs* are due to stenosis or incompetency of one or more of the valves of the heart.

Functional murmurs are not due to valvular disease.

Organic murmurs may be systolic or diastolic; may be accompanied by marked dilatation or hypertrophy, may be transmitted, and there will probably be a history of rheumatism or of some other disease capable of producing endocarditis. Whereas a murmur, usually systolic, soft and blowing, heard best over the pulmonary area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a *hemic* or *functional* murmur, and denotes as a rule an impoverished condition of the blood.

4. *Respiratory symptoms in influenza*.—Coryza, angina, and tonsillitis may be present; laryngitis sometimes occurs, with hoarseness. Tracheitis causes pain, tenderness, and severe paroxysmal cough, induced by irritation at the tracheal bifurcation. Bronchitis is diffuse or occurs over one lung or lobe. The sputum is characteristically nummular and greenish-yellow. It is often blood-stained, viscid, and contains the bacillus. Rales abound near the liver and lingual lobe. . . . Influenza pneumonia, strictly speaking, shows no fibrinous exudation or granulations, but is *catarrhal*, with infiltration of cells about the bronchi as discrete foci. Clinically, the pneumonia is *atypical* and begins without a chill, but with insidious increase of the prior cough and dyspnea. It usually develops during or after the influenza attack, although pneumonia may be the first sign of influenza. Its symptoms are more pronounced than its physical signs, and the disproportionate cyanosis and dyspnea sometimes suggest miliary tuberculosis. Foci of dulness may be found but distinct bronchial breathing is rare; bronchophony is a much more reliable symptom. There may be slow breathing with difficult, prolonged expiration. The heart is often weak and a peculiar redness of the face and head, profuse sweats at the beginning, and characteristic paroxysmal coughing are symptoms not seen in ordinary pneumonia. The foci are bilateral or multiple in 60 per cent. of cases and the apices are involved frequently. The sputum is purulent or bloody.—(From Edwards' *Practice of Medicine*.)

The *Treatment of pneumonia* "depends entirely on the type of case, and the condition of the patient. Routine treatment is the worst of all treatments. Answer the following questions before prescribing: Is the patient full-blooded, and is there present a full bounding pulse? Is the pulse feeble, irregular, or intermittent?"

"In the first case, in a young and previously healthy adult, if there be cyanosis, or signs of dilatation of the right heart, blood-letting to the extent of a few ounces may perhaps relieve the strain, but more generally treatment should be directed to maintaining the strength from the outset.

"In the latter case we can hope for nothing from a depressing treatment, so stimulants must be resorted to, such as alcohol, ammonium carbonate, egg and brandy mixture, quinine, ether, etc. The giving or withholding of alcohol depends upon its effect upon the pulse; should the pulse rate fall and the tongue become moist it may be continued. In asthenic cases, strychnine hypodermically is necessary from the outset, and normal saline may be given by the rectum or by the skin. Oxygen inhalations are used where there is cyanosis, but it is doubtful whether they have saved many lives. When there is evidence of failure of the heart (weakness of the second pulmonary sound, etc.) digitalis should be resorted to. Many prescribe it from the outset.

"The diet should consist of milk, beef-tea or broths, white of egg, and so on. The patient should be as little moved as possible, and the bed-pan must be used. As in other fevers, an airy room and good nursing are essential.

"Remember that narcotics are not well borne in respiratory embarrassment as a rule. Chloral should be avoided, but if *pain be excessive* a hypodermic injection of morphine does more good than harm, notwithstanding that theoretically morphine is contraindicated. It should not be given later than the first few

days of the illness. The pain may also be relieved by poultices, which, however, are of doubtful use if carelessly made, or by application of ice. Cold packs applied to the trunk only, and frequently repeated, are very useful in relieving both pain and fever. Depressant antipyretics are to be avoided."—(Wheeler and Jack's *Handbook of Medicine*.)

5. In *Chronic interstitial nephritis*, the patient "must be cautioned not to expose himself to the inclemencies of the weather, to avoid all excessive muscular exercise and all mental worry; he must have his bowels open at least once daily (alkaline mineral waters, saline cathartics, occasional blue mass pill, etc.); and he must favor the action of the skin so as to relieve the subnormal cardiovascular-renal system; warm or hot baths are serviceable, but they are contraindicated if they cause unpleasant throbbings (increasing blood pressure). The diet is of the utmost importance, the duration of life probably depending more upon discretion in eating and drinking than upon any other factor. In many cases an exclusive milk diet for a time (four to six weeks) is desirable; and it may be repeated from time to time. In general the diet should be sufficiently varied to be attractive, it should be free from irritating qualities and readily assimilable, and the nitrogenous constituents should be relatively reduced. The meat allowance should not exceed 100 grams daily; a diet of ample fuel value should be constructed by adding a sufficiency of fats and carbohydrates; an excess of meat is said to favor the development of uremia; red and white meats are of equal value, and may be allowed in accordance with the patient's desires. As a rule, alcohol should be prohibited, although in some cases a little of the lighter wines appears to do no harm. In many cases the foregoing produces not only amelioration of the symptoms, but perhaps also arrest of the lesions; if so, other measures are not required."—(Kelly's *Practice of Medicine*.)

Drugs are not of much value. (1) *Nitroglycerin* lowers arterial tension; (2) *iron* may be of benefit in pronounced anemia; (3) *aconite* may help when nitroglycerine fails.

Respiratory complications.—Dyspnea, Cheyne-Stokes breathing, hydrothorax, edema of larynx, pleurisy, pneumonia, bronchitis.

Nervous complications.—Headache, insomnia, drowsiness, apoplexy, meningitis, convulsions, coma, epilepsy.

6. *ACUTE CEREBROSPINAL MENINGITIS*.—*Diagnosis* is made from (1) the symptoms, (2) Kernig's sign, and (3) lumbar puncture. *Symptoms*. The onset is generally sudden, with headache, rigors, stiff neck, opisthotonos, vomiting, moderately high (102° F.) and irregular fever, full and rapid pulse, herpes, photophobia; convulsions, delirium, monoplegia or hemiplegia, enlarged spleen, retracted abdomen, and disturbed reflexes may be present. *Kernig's sign* is obtained (if the thigh is flexed at right angles to the abdomen, the leg cannot be fully extended on the thigh, as it can in health, owing to the contraction of the flexor muscles). By *lumbar puncture*, some of the cerebrospinal fluid may be withdrawn and examined for the presence of the diplococcus.

Treatment.—"When there is marked collapse in the early stages, warmth, stimulants, and mustard may be used; later, the indications are to subdue the spinal irritation and to relieve pain. To meet the former, atropine or belladonna, bromides or ergot may be given; for the latter, opium is mainly to be relied upon, and must often be freely used. Leeches to the nape of the neck, and ice to the head are also useful, and an ice-bag may be applied along the spine. Blisters to the spine are advocated by many. Repeated withdrawal of cerebrospinal fluid by lumbar puncture is often of use, at least in relieving symptoms due to pressure, and may lead to cure. When the fluid is purulent, antiseptic solutions (10 cc. of a 1 per cent. lysol solution) may be injected after its removal.

Serum treatment.—"Flexner's antimeningococcic serum has been used with considerable success; 50 cc. of cerebrospinal fluid being withdrawn, 30 cc. of the serum are injected. This may be repeated daily for four days."—(Wheeler and Jack's *Handbook of Medicine*.)

SURGERY.

1. FRACTURES OF THE FEMUR.—“*Intracapsular fracture* most commonly occurs in people over fifty, especially women, owing to senile changes in the bone rendering it brittle. As a rule, indirect violence is the cause—e.g. slipping off a curb or catching the toe in a carpet. The patient falls, and is unable to walk or raise the limb. The head may be held at first by the reticular fibres. If impaction, which is uncommon, occurs, the neck is driven into the head. The displacement consists of drawing up of the lower fragment and external rotation. The rotation is due to the weight of the limb and to greater breaking up of the posterior surface than of the anterior. Shortening is rarely more than three-quarters of an inch. Treatment.—Fibrous union nearly always occurs in old people, as the blood supply of the upper fragment depends solely on the obturator branch running in the ligamentum teres. Then, old people often die of hypostatic pneumonia if kept lying long upon the back. If the patient be young, he should be put upon a long Liston splint, with extension, for six weeks. The same should be tried with old people, but the moment the respirations begin to increase the patient must be got up, wearing a Thomas's hip splint. Impaction favors bony union, and so should not be broken down.

“*Extracapsular fracture* means fracture of the neck near the trochanter, and often is associated with splitting up of the trochanter. The usual cause is a heavy fall on the great trochanter, and impaction is common. Shortening always occurs, up to as much as 3 inches; external rotation of the limb is always present, and if there is impaction the trochanter is broadened.

“*Signs and Symptoms of Fractures of the Neck.*—1. Pains, bruising, and swelling are more marked in extracapsular fractures. 2. Crepitus is present in the unimpacted fractures. 3. Loss of power usually occurs in both, but patients have walked with impacted fractures. 4. Eversion is a striking feature in both. 5. Shortening is much more marked in extracapsular fractures. 6. The position of the great trochanter is altered. It is raised, everted, nearer to the mid-line, and rotates in the arc of a smaller circle than the opposite one.

Its position is demonstrated as follows: *Nélaton's line* is drawn from the anterior superior iliac spine to the tuber ischii. The top of the trochanter should touch this line if the limb is placed in the axis of the body. *Bryant's line*: Drop a vertical line to the bed from the anterior superior spine, and measure off the length of a line running at right angles from this to the trochanter, and compare it with a similar line on the sound side. *Morris's bitrochanteric test*: Measure and compare the distances of the trochanter from the mid-line. 7. Broadening of the trochanter only occurs in extracapsular fracture. Treatment. Unless there is great deformity, it is not advisable to break up impaction. Bony union always occurs. The patient should be anesthetized, and traction kept upon the leg during fixation. A stirrup extension is first put on, and then the leg is firmly bandaged to a long Liston splint, with the eversion corrected. The chest is fixed to the splint by a binder; the foot of the bed is raised, and a weight of 8 or 10 pounds is put on to the cord of the stirrup extension. Hodgson's splint may also be used. Union occurs in six weeks.

“*Fracture of the great trochanter* without fracture of the neck is very rare. If the fragment is displaced, it should be wired or pegged.

“*Separation of the epiphysis* of the head of the femur resembles intracapsular fracture. Impairment of growth may follow.

“*Fractures of the shaft of the femur* may be due to either direct or indirect violence. The displacement varies according to the situation and obliquity of the fracture. In the upper third the upper fragment is flexed, abducted, and rotated out by the psoas, iliacus, and glutei, while the lower is drawn up and adducted by the adductors, and rotated out by its own weight. In the middle third the displacement is less marked. In the lower third the lower fragment is often tilted backwards by the gastrocnemii, and may puncture, compress, or rupture, the vessels and cause gangrene. Treatment.—In fractures near the upper or lower ends,

the smaller fragment, as a rule, is tilted, and cannot be controlled by an ordinary splint, so the longer fragment must be placed in a plane corresponding to that in which the shorter lies. For this purpose Macintyre's and Hodgson's splints are useful. In the middle third, extension and a long Liston splint, with a short Gooch splint over the inner part of the thigh. For children a double Bryant splint is necessary. The ‘gallows’ splint and plaster are also useful for children.

“*Supracondylar Fracture* is the same as fracture in the lower third.

“*T-shaped Fracture of the Lower End* separates the two condyles, as well as produces transverse fracture above them. The condyles can be moved on one another, with crepitus, and the joint is rapidly distended with blood. The only satisfactory treatment is to open the joint and peg the condyles together.

“*Separation of either Condyle* produces distention of the joint with blood, abnormal lateral mobility of the knee-joint with crepitus, and perhaps deflection of the leg to the injured side. The leg should be put in plaster after reduction; but the most satisfactory treatment is operation and mechanical fixation.

“*Separation of the Lower Epiphysis* is rare, and simulates transverse fracture; but the epiphysis is displaced forward, and the diaphysis may compress the popliteal artery. The injury is often compound. Reduction by traction and manipulation should be performed, and the limb put up fully flexed without a splint. The limb is fixed by a bandage and laid on its outer side, with an ice-bag over the knee. In a fortnight passive movement is begun.” (*Aids to Surgery*.)

2. EMPYEMA. Etiology: Wounds, injuries, pleuropneumonia, direct extension of a suppurative process in the lung, abdomen, or neck. The bacteria will vary with the cause; *Diplococcus pneumoniae* is the commonest; tubercle bacillus, staphylococcus, streptococcus, *Colon bacillus* may also be present.

The physical signs are those of fluid in the pleural cavity; that side does not move well, the percussion note is dull, there is absence of breath sounds, vocal fremitus and resonance are diminished. Left alone, an empyema may burst through an intercostal space, usually the fifth. The lung is collapsed in extent according to the amount of pus. The pleura, at first covered with lymph, soon becomes covered with layers of granulation tissue, the deeper part of which is converted into fibrocartilaginous tissue, and the lung itself also undergoes some fibroid change. If the pus is let out early the lung and pleura soon expand, but if allowed to go on the infiltration of the lung and the density of the scar tissue covering it hinder expansion. Nature attempts to remedy this in various ways: (1) The other lung expands and pushes the heart over to the opposite side; (2) the chest wall falls in, the intercostal spaces are obliterated, and the spine is curved, with its concavity toward that side; (3) the abdominal viscera are pushed up; and (4) exuberant granulations form on the pleura. If a cavity still remains an operation is necessary.

Symptoms: Fever, sweats, chill, diminished breath sounds and vocal fremitus, impaired mobility of chest, dullness on affected side, heart displaced to opposite side, leucocytosis.

Treatment: “Treatment should be undertaken without delay. Aspiration seldom cures, but may be undertaken where the dyspnea is great, and an anesthetic given afterward for the excision of a piece of rib. Drainage is always necessary, and is best done by excising a portion of the fifth or sixth rib in the mid-axillary line. The patient should be allowed to come round quickly from the anesthetic, so that the coughing which occurs will expel the masses of coagulated lymph and help to expand the lung. A big drainage-tube is then inserted. Daily dressings are necessary, but irrigation of the cavity is seldom needed. If, because of delay in treatment, the cavity does not soon close, Estlander's operation, or some modification, must be performed. The wound must be enlarged and a number of ribs exposed, and sufficient of them removed to convert the cavity into a pyramidal one, the base of which is the open wound. This is packed with gauze and allowed to heal from the bottom. If the operation

has to be extensive, the flaps are allowed to fall back upon the granulating surface of the lung, and in these cases marked scoliosis and weakness of that side of the chest follow."—(*Aids to Surgery*.)

3. "Gall-stones are rare in young subjects, but are commonly met with after middle age, especially in women. They consist of cholesteroline crystals, bile pigment, and bile salts, with a nucleus of inspissated mucus. When multiple stones are present they are faceted.

"Causes.—Retardation of the bile flow from the pressure of corsets, a sedentary life or irregular meals, and especially constipation, are the predisposing causes; then follows infection from the intestine, by the colon or typhoid bacillus setting up catarrh of the gall-bladder. Cholesteroline and pigment are now deposited, and give rise to stones. Gall-stones are commonly found in cases of carcinoma of the gall-bladder.

"Course.—Gall-stones only give rise to symptoms—(1) when they try to escape; (2) when they hinder the escape of bile; and (3) when they cause cholecystitis.

"Symptoms are entirely absent in many cases. Pain in the right hypochondrium is a common symptom, and is more often due to attacks of cholecystitis than to biliary colic. If the patient is examined during an attack, a distended gall-bladder projecting below the costal margin at the tip of the eighth or ninth costal cartilage may be felt. It forms an elastic tumor, moving with the liver on inspiration and dull to percussion.

"Biliary Colic is due to the passage of a stone along the bile-passages. It varies from slight pains, usually ascribed to stomach-ache, to the most agonizing colic, beginning in the right hypochondrium and accompanied by vomiting. The pain continues till the stone reaches the intestine or passes back into the gall-bladder. Some tenderness and slight jaundice usually follow for a few days, but jaundice is not present if the stone does not reach the common duct. These attacks recur at varying intervals, and should be treated by hot fomentations and the hypodermic injection of $\frac{1}{4}$ to $\frac{1}{2}$ grain of morphine.

"Impaction of a Stone.—When the stone lies in the cystic duct, the gall-bladder is usually distended with mucus and some bile; there is a varying amount of pain, but no jaundice. When the stone lies in the common duct, the pain and tenderness are more marked, and there is always jaundice, which, however, varies in intensity from time to time. A stone impacted in the lower end of the duct may ulcerate into the duodenum; higher up it may ulcerate into the colon or into the peritoneal cavity, producing peritonitis, or into the retroperitoneal tissues, producing an abscess."—(*Aids to Surgery*.)

The following list of complications is given by Robson: "Intestinal obstruction due to localized peritonitis, volvulus, adhesions, or large gall-stones which have ulcerated into the bowel; general hemorrhages, the result of chronic jaundice; adhesions causing pain, even after gall-stones have been removed, or dilatation of the stomach; fistula into neighboring viscus or to the surface of the body; stricture of cystic or common duct; abscess (liver, kidney, pericystic, abdominal wall, subphrenic, pancreas); cholangitis, simple or suppurative; septicemia or pyemia; phlegmonous or gangrenous cholecystitis; perforative peritonitis; cancer of the gall-bladder or ducts; pneumonia of the right lung or empyema of the right pleura; acute or chronic pancreatitis; cirrhosis of liver."

4. "Acute dilatation of the stomach is a sudden paralytic distention of uncertain origin, but probably the result of disturbed innervation. About 40 per cent. of the cases arise after operations, usually on the upper abdomen (hence shock, sepsis, purgation, handling of the viscera, and the anesthetic have been held responsible); 20 per cent. during exhausting fevers (typhoid, pneumonia, etc.), 10 per cent. after errors in diet, particularly the ingestion of enormous quantities of food or drink, and the rest as the result of trauma, emotional attacks, childbirth, peritonitis, and spinal deformity, especially when there is lordosis, which may encourage pressure on the duodenum. The enormously dilated stomach forces the small intestine into the pelvis and renders its mesentery taut. As a

consequence the duodenum is compressed between the root of the mesentery and the superior mesenteric vessels in front and the vertebral column behind. Some surgeons regard this constriction of the duodenum as primary, hence the terms *gastromesenteric ileus* and *arteriomesenteric occlusion*. Even if this is not true, it is certain that a secondary factor is thus added which serves to augment and perpetuate the condition. The symptoms are pain; profuse vomiting; severe thirst; distention of the stomach, which interferes with the action of the heart and lungs, and which may be so great as to fill the whole abdomen; gastric splashing sounds on succussion; constipation, perhaps with clay-colored stools; scanty urine; and finally collapse, with, if proper treatment is not quickly administered, death in two-thirds of the cases. The diagnosis from peritonitis is made by the absence of fever, leucocytosis, tenderness, and rigidity. In high intestinal obstruction there is little distention.

"The treatment is gastric lavage; placing the patient on the right side with the pelvis elevated, in the knee-chest posture, or prone, in order to relieve the duodenum of pressure; salt solution subcutaneously or intravenously; strychnine, atropine, or eserine salicylate hypodermically; electricity to the epigastrium; and, as a last resort, gastroenterostomy."—(*Stewart's Manual of Surgery*.)

5. "The chief dangers of compound fractures are, firstly, *hemorrhage*, the blood, instead of collecting within the tissues of the limb, escaping externally if a sufficient opening is present; otherwise subcutaneous extravasation occurs, as in a simple fracture; and, secondly, the advent of *infection*. The latter is the more important, and may lead to the most serious consequences. Portions of muscle and periosteum, which in a simple fracture would be absorbed or incorporated in the callus, become infected, and may slough. Small isolated fragments of bone are almost certain to necrose if suppuration ensues, while acute osteomyelitis may occur, leading to extensive necrosis, and even endangering the patient's life by pyemia. Joints may be infected, and acute suppurative arthritis result; and secondary hemorrhage may follow an infective peri-arthritis. Such results are more likely to follow when the external wound is small and insufficient provision has been made for drainage."

"In the treatment of compound fractures the main object is to render the wound aseptic and to give efficient exit to the discharges. For this purpose the patient should in all cases be anesthetized, the limb shaved, and thoroughly purified, and the wound enlarged and thoroughly washed out with some reliable antiseptic. It may be advisable to excise torn and dirty fragments of skin, muscle, and tendon, especially when dirt has been ground into them. Loose fragments of bone are removed and portions denuded of their periosteum may be taken away lest necrosis should ensue; where fragments retain any considerable connection with the soft parts they may be left without fear. When a sharp end of one of the fragments is protruding through a small opening in the skin it is first purified thoroughly before attempting its reduction and then replaced after enlarging the wound in the skin, or a portion sawn off. Hemorrhage is dealt with in the usual way, and the fragments are placed as nearly as possible in their normal position. If the fragments can be brought accurately into position it is well to fix them by some mechanical appliance; but where the ends of the bone are much comminuted the small portions must be arranged in position as well as possible, and no attempt made to wire them. A good-sized drainage tube is inserted, and, if need be, counteropenings are made; the external wound is closed or not, according to circumstances, and dressed, and suitable splints are then applied. Under such a régime the majority of cases do well. Immoveable apparatus may be used after a time, windows being left in the plaster cast to allow wounds to be dressed."—(*Ross and Carless' Manual of Surgery*.)

6. URETHRAL STRICTURE.—Three forms of stricture are described, spasmodic, congestive, and organic.

"Spasmodic and Congestive Strictures frequently co-exist, although either congestion or spasm may be the predominant feature in any particular case. Thus, in acute gonorrhea the mucous membrane often becomes

engorged and thickened to such an extent as to interfere with the act of micturition. Spasm is the chief element under the following conditions: (1) When a patient, suffering from slight organic stricture, is exposed to wet or cold, especially after heavy drinking; (2) after operations on the rectum or spermatic cord; (3) as a result of catheterism; and (4) from perineal irritation of the urethra, as by a blow or kick in this region, or from prolonged riding on a bicycle with a badly-fitting saddle or on horseback.

"Organic Stricture is the term applied to an undilatable condition of the urethra, resulting from the development of cicatricial tissue within its walls. The Causes of organic stricture are: (a) The long continuance of a urethral discharge, following gonorrhea, or the frequent recurrence of this affection. Chronic inflammations are always characterized by a tendency to sclerosis of the tissues involved, and the urethra is no exception to this rule, its walls under these circumstances becoming thickened, indurated, and contracted. (b) The cicatrization of a urethral chancre, or of an ulcer caused by the impaction of a stone, or the contraction produced by the healing of a urethral abscess, may also lead to stenosis. (c) The most intractable forms of stricture are those due to cicatrization after rupture or laceration of the urethral wall. The usual Situation is within the bulb, i.e., just in front of the triangular ligament; but the orifice and body are not infrequently affected. It occurs in the membranous portion only as a result of traumatism, and never in the prostatic. To find more than two strictures in any particular case is unusual, although three or four have been met with."—(Rose and Carless' *Manual of Surgery*.)

BULLETIN OF APPROACHING EXAMINATIONS.

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION
Alabama	S. W. Welch, Montgomery	Montgomery, July 12
Arizona	A. Martin, 207 Goodrich Building, Phoenix	Phoenix, April 5
Arkansas	C. B. Pinkham, Little Rock	Little Rock, May 10
California	C. B. Pinkham, Sacramento	Los Angeles, Feb. 14
Colorado	David A. Strickler, Empire Building, Denver	Denver, April 6
Connecticut	R. E. Rowley, Hartford	Hartford, March 8
Delaware	H. W. Briggs, Wilmington	Wilmington, June 21
Dist. of Col.	E. P. Copeland, Washington	Washington, April 12
Florida	M. W. Rowlett, Tampa	Jacksonville, June 13
Georgia	C. T. Nolan, Marietta	Jacksonville, June 13
Idaho	Edmt. O. Jones, Boise	Boise, April 5
Illinois	F. C. Dodds, Springfield	Chicago, Feb. 28
Indiana	W. T. Gott, Crawfordville	Indianapolis, May 10
Iowa	G. H. Sumner, Des Moines	Des Moines, May 10
Kansas	H. A. Dykes, Leavenworth	Topeka, May 10
Kentucky	J. N. McCormack, Louisville	Louisville, May 10
Louisiana	E. W. Mahler, New Orleans	New Orleans, May 10

Miscellany.

The First Centenary of the Paris Academy of Medicine.—Brochin, writing in the *Gazette des Hôpitaux* for December 18, 1920, xciii, 106, indulges in reminiscences of the Paris Academy of Medicine, which was organized in December, 1820. The new body represented a consolidation of the old Academy of Surgery and the Royal Society of Medicine. The first few years the meetings were held in the Louvre and then during the period 1824-1850 the society leased a building in the Rue de Poitiers. When in September, 1850, it moved into the old chapel of Charité Hospital there were solemn ceremonies. This building proved to be its home for more than 50 years. In 1902 it moved into its present quarters in the rue Bonaparte. The first president of the Academy was Portal and among his earlier successors we note the names of Dupuytren in 1824, Lisfranc, 1835, Belpeau, 1849, Orfila, 1851, and Cruveilhier, 1859. Many of the older presidents are forgotten today. Brochin remembers when Malgaigne was president and among his successors recalls Bouchardat, Tarnier, Jaccoud, Guyon, Tillaux, Dieulafoy, Lannelongue, Hayem, Delorme, and many others of equal or lesser note. Several eminent men almost failed to become members, including Labbé and Péan. The latter had a way of presenting specimens instead of patients which roused considerable opposition. The Academy was naturally conservative and in passing on the great questions of the day was often slow in accepting new discoveries. This was the case when Villemin read his paper on the contagion of tuberculosis, and Pasteur's early work roused the most violent opposition. The author states that the systematic opposition to all new developments proved a blunder and in the case of Pasteur it went to extremes. When we consider how quickly the latter's views made good it is hard to realize the attitude of many of the leaders of the Academy. It was argued for example that a mere chemist could know nothing of medicine.

Medical journalism has played a considerable role in the history of the Academy. Originally the journalists had a special bench, but on the removal to a new building in 1850 they were compelled to use the common seats. A protest led to the resumption of the old order. Many of the former journalists are mentioned by name, with the periodicals represented, these including some of the lay journals. Not a few of these men were also eminent as practitioners and scientists. We note the names of A. Broca, Dujardin-Beaumetz, and Guérin, famous as the enemy of Pasteur. When the society moved to its present quarters, the journalistic force, which then comprised 15 or more men, including secular reporters, were relegated to a corner where they were out of touch with the members and where the poor acoustics rendered their work difficult. Despite all dissatisfaction volubly expressed the officers compelled them to remain in the "chicken coop" as it was called until recently, when the present president Richelot, who was once a journalist, intervened to make the situation more tolerable. The author in closing styles himself "a friend of the Academy but a greater friend of truth."

THE POSSIBLE RELATION OF THE ADRENAL CORTEX TO GRAVES' DISEASE AND TO MYXEDEMA.*

By G. A. FRIEDMAN, M.D.

NEW YORK.

CLINICAL PROFESSOR OF MEDICINE, NEW YORK POLYCLINIC HOSPITAL AND MEDICAL SCHOOL; VISITING PHYSICIAN, BETH DAVID HOSPITAL; GASTROENTEROLOGIST, GOUVERNEUR HOSPITAL.

MUCH has been written about the rôle of the adrenal medulla in Graves' disease, but the adrenal cortex apparently remains a *noli me tangere*. The reason is obvious: little is known about the physiology of the cortical portion. But it seems that with increased, though fragmentary, knowledge of the suprarenal cortex obtained in recent years, a better understanding may be reached as to its possible rôle in some endocrine disorders. Before approaching our theme, a few remarks are essential in regard to the relation of the adrenal medulla to Graves' disease and to myxedema.

The symptoms and signs which have led the clinician to suspect overactivity of the medulla in hyperthyroid states are as follows: the occasional hypertension, the tremors, the tendency to alimentary glycosuria, and perhaps the phenomenon of exophthalmos. That exophthalmos is due to excesses of epinephrin and not to excesses of thyroid, was emphasized by Maurice¹ of Lyons. The sensitiveness of hyperthyroid subject to epinephrin injections or to the well known Goetsch test; the sensitiveness to the same test of individuals afflicted with diffuse adenomatosis of the thyroid, a clinical entity recently discovered by Goetsch;² the findings of increased amounts of epinephrin by Adler,³ Fraenkel,⁴ and others in the blood serum in exophthalmic goiter cases, are the corroborative evidences furnished to the clinician by the laboratory.

It is true, however, that the epinephrin content in the medulla, as Elliott⁵ writes, has never been found increased in any morbid condition, especially in Graves' disease. Elliott emphasizes the dependence of epinephrin losses in the medulla upon post-mortem changes. Thus the low epinephrin contents found in the medulla in exophthalmic goiter cases do not disprove the hyperfunction of the medulla in hyperthyroid states. Pettavel⁶ found in the majority of cases of Graves' disease large cells with large nuclei in the medulla. He sees in these histological changes a partial cellular hypertrophy and inasmuch as these findings were present in the medulla of

Basedow cases with adrenals of normal weights, he concludes that the overactivity of the medulla in hyperthyroid states must be of a mild grade. Pettavel's findings are in perfect accord with Goetsch's discovery that hyperthyroid individuals are sensitive to epinephrin injections. The reverse condition, hypofunction of the adrenal medulla, may possibly hold good for myxedematous individuals.

It is known from experiments that the renal vessels are more sensitive to epinephrin than the vessels of other organs. Epinephrin injections dilate the vessels of the kidneys. Perhaps the frequent polyuria in Graves' disease may be explained by the diuretic effect of epinephrin. The diminished diuresis in myxedema may, then, be due to diminished epinephrin secretion.

The high sugar tolerance in thyroidectomized animals, the effectiveness of epinephrin injections to cause glycosuria in such animals, as shown by Eppinger, Falta and Rudinger,⁷ the absence of glycosuria after injections of the drug in individuals afflicted with Addison's disease, the hypoglycemia in myxedema, as well as in Addison's syndrome are facts suggestive of a possible mild hypofunction of the adrenal medulla in myxedema. Furthermore, eosinophilia is frequent in Addison's disease. In four out of six of my patients afflicted with Addison's disease, in whom blood counts were made, eosinophilia was a marked feature. Wolf and Thacher⁸ found that the eosinophiles in Addison's disease ranged between 10 and 20 per cent. Hyper-eosinophilia in myxedema was reported by Lebreton and Vaquez,⁹ Bence and Engel,¹⁰ Falta¹¹ and others. That eosinophilia in myxedema may actually be due to a deficit in epinephrin secretion is highly probable because intravenous injections of epinephrin in animals lead to eosinophilia.

Necropsy reports of myxedematous individuals in regard to the suprarenals are meager, as one may convince himself by searching through the literature. In the pre-thyroid era little attention was paid to the suprarenals. In recent years, on account of the beneficial results of substitution therapy, autopsies in myxedematous individuals are rare. Hun and Prudden¹² found the adrenals atrophied in two cases of myxedema.

From all these considerations, it seems possible to assume a mild deficiency of the adrenal medulla in myxedema. The reason why this adrenal deficiency in myxedema remains hidden from the clinician will be discussed later. The object of this paper is to show that the adrenal-cortex plays an important rôle in hyperthyroidism and in myxedema, and that the share of the cortex in Graves' disease differs from that in myxedema.

*Read before the Harlem Medical Association, November 4, 1920.

Embryology suggests that the function of the cortex may be entirely independent of that of the medulla. The cortex originates from the peritoneum, the medulla from the sympathicus. While it is known that the adrenal medulla has endocrine properties, the same does not hold true so far for the cortex. It is an established fact that the cortex and not the medulla characterizes the higher animals. When the cortex in the fetus remains undeveloped, corresponding to such a stage as in lower animals, the child is born without cerebral hemispheres. In the anacephalic child the rest of the body is normally developed. Such influences are ascribed to hormones.

It is known that in fish the cortex is entirely isolated from the medulla. Inasmuch as it is generally believed that the medulla receives its raw material for elaboration of epinephrin from the cortex, in fish, the latter must unload its material for the medulla through the general circulation. This process reminds one of the workings of duodenal secretin upon the pancreas. This is also suggestive that the cortex has some properties common to endocrine glands.

The adrenal cortex under physiological conditions is the richest organ in lipoids; it also contains pigment, which is iron free. The French believe that the cortical portion represents the factory for the lipoids; the Germans consider the adrenal cortex as a storehouse for the lipoids drawn from the tissues through the blood stream.

Although some experiments were performed to show that the cortex and not the medulla is essential to life, this has not been generally accepted. It is probable that both are equally essential. One must assume, in the present state of our knowledge, that the functions of the cortex and the medulla are dependent and interdependent. This means that some functions ascribed to the suprarenal gland are chiefly carried out by the cortex, others by the medulla, and again, others by both portions. The cortex and the medulla possess an accessory apparatus. The accessory glands, belonging to the interrenal system, have the same histological structure and the same properties. They may justly be called emergency apparatuses, and so may the adrenal system, with its ganglia which possesses chromaffine properties. The greater importance of the cortex may possibly be assumed from the well-known fact that cortical tissue is found in the medulla; also occasionally in the kidneys; but medullary substance has never been found in cortical tissue.

There is not a single case on record in which life was possible without a cortex; but there are recorded cases which show that in some individuals the medulla was absent. Complete absence of the medulla was found by Ulrich¹² in a man, aged 72. Klebs¹³ reports an autopsy of a young and robust man, aged 20, who died from pneumonia, that revealed the presence of cortex only. One must assume that other members of the adrenal system furnished the necessary medullary epinephrin in these individuals. The cortex, according to Elliott,¹⁴ is completely devoid of epinephrin, and it is not under control of the splanchnic nerves, as proved by the same author.¹⁵

The fact that the cortex and the medulla are united to form one organ in man and other higher

animals, and not separated as in fish, shows that such arrangement is necessary for the harmonious working of both suprarenal portions. Each gland in normal individuals weighs from 4 to 5 grams, with an epinephrin content of 4 to 5 mngs. The cortex composes 90 per cent. of the gland; the medulla, 10 per cent. Both glands weighing about 10 grams, contain 1 gram of medullary substance with 10 mngs. of epinephrin. In order that the tissues of the body remain in a physiological epinephrin equilibrium, the medulla must produce more or less constantly this amount of epinephrin. The medulla probably receives material for the elaboration of epinephrin directly or indirectly from the cortex.

According to the studies of Flint,¹⁶ Srdinko and Landau,¹⁷ the cortex and the medulla have a common vascular system; the medulla in addition has an independent branch from the cortex with the general circulation. The cortex may pour its material for elaboration of epinephrin directly into the bloodstream, as in fish. In man, the communication between the cortex and the medulla is probably a direct one. The blood of the body, according to Poll,¹⁸ which has become deprived of its epinephrin contents by the tissues, is carried by the vessels which serve the medulla directly to the epinephrin-forming cells; the latter give off their elaborated secretion and the blood, with its renewed epinephrin load, is again returned to the general circulation. The medulla receives material for the epinephrin through the venous blood discharged from the cortex, the latter containing the products of metabolism of this tissue. These adrenal cortical products constitute the raw material for elaboration of the medullary secretion.

Thus the chief function of the cortex seems to consist in supplying the medulla, either directly or indirectly, with its products for the elaboration of epinephrin. The second function of the cortex is probably a detoxicating one. Myers¹⁹ has shown that cobra toxin loses its toxicity if mixed with an emulsion of suprarenal cortex, but that its toxicity is unchanged by an emulsion of suprarenal medulla.

What are the poisons which the cortex must detoxicate and what is the nature of the raw material which the cortical portion furnishes the medulla for the elaboration of its secretory product? According to the recent investigations of Bauer,²⁰ the cortex detoxicates the waste products of the intermediary metabolism which are present in the circulation even under physiological conditions. The chief product of the purin metabolism presents uric acid. The latter, according to Bauer, is also the mother substance of pigment. The melanin of the cortex, or oxidized uric acid, is elaborated into epinephrin by a process of destruction and by repeated processes of reduction in the medulla. Thus the oxidation of uric acid in the cortex serves a double purpose: to keep the pigment in the cortex in equilibrium, and to oxidize the raw material for the medulla. Bauer quotes Meirovsky²¹ who emphasized long ago that the adrenal glands regulate the metabolism of pigment in the skin by decomposing certain products of epidermal layers like tyrosin and its derivatives. Neuberg²² went even further and showed that the tryptophan group with tyrosin, p-oxyphenylethylamin and adrenalin belong to the

substances of the animal body from which melanin forms through enzymatic processes.

Inasmuch as Bauer's theory presents the basis for the contention defended in this paper, a few remarks are essential in considering the working hypothesis which led him to his conclusions. Bauer found the adrenals very large in individuals who died from nephritis, especially in those in whom contracted kidneys were found at necropsies. While the weight of the adrenals normally averages about 10 grams, they amounted in his nephritics to as high as 18 grams. Simultaneously with the large size of the suprarenal glands, the cortex was unusually broad and it showed a pronounced increase in pigment. Similar findings were also noted by him in those cases of Addison's syndrome in which there were no gross anatomical changes in the gland. Obviously, when suprarenal glands are destroyed by caseation, as in the majority of cases of Addison's disease, an accessory adrenal having the same function as the cortex, may hypertrophy and work vicariously for the destroyed cortex. He claims that since kidneys, according to our present state of knowledge, do not possess nerves regulating their function, the renal function depends solely upon the physics of the general circulation, *i.e.* upon the velocity of the blood current and upon the height of the blood pressure. Furthermore, he refers to the previously mentioned fact that the renal vessels are the most sensitive to epinephrin. The greater the amount of purin bases in the blood, the more epinephrin is formed. He compares the adrenals to a ventilanometer which, under physiological conditions, prevents the accumulation of toxic uric acid in the body and in such a manner saves the organism from uremia. In this sense the cortex, especially the interrenal system, has a detoxicating function.

In case the interrenal system has become overworked from binding and oxidizing the uric acid in severe cases of nephritis and cannot fulfill its function, the uric acid is deposited in the skin, where it may become oxidized to pigment. From individuals who died from severe nephritis with uremia, Bauer excised pieces of skin 24 to 48 hours after death, fixed them in alcohol and let them remain in the incubator in bottles filled with distilled water at a temperature of 56 to 60 degrees for three days. The same procedure was carried out with the excised skin from bodies of individuals who did not show any pathology in the kidneys and who did not have during life any symptoms or signs of nephritis. His results were uniform: while the skin from the uremic cases showed on the first day a marked brown color which grew more intense on the third day, the skin from the controls showed no change in color during the whole procedure.

Bauer also demonstrated, by the most accurate microchemical tests, uric acid in all sympathetic ganglia, its absence in non-sympathetic ganglia, and its presence in the cortex, chiefly in the pigment zone.

Mirovsky proved that the pro-pigment of melanin was present in the skin of individuals who died from Addison's disease and that the skin of the bodies required only oxidation over water of a temperature of 56° C. in order to show distinctly the phenomenon of pigmentation. The skin

from individuals who died from various other diseases did not assume a brown color after the same procedures. The hyperpigmentation of the skin in the Addison syndrome, one of the cardinal symptoms, is due to excessive accumulation of uric acid in the blood which is deposited and oxidized in the skin.

That there is a marked retention of purin bases in the blood in Addison's disease was shown by Wolf and Thacher,²² who found that the retention of creatinin and uric acid in this condition was pronounced. The accumulation of uric acid in Addison's disease has two causes: (1) the cortical material cannot be utilized for the elaboration of epinephrin and (2) the deficiently functioning cortex has to oxidize still more uric acid.

When the cortex has been completely destroyed, as in some cases of Addison's disease, by tuberculosis, an accessory gland may temporarily perform the function of oxidation. Ultimately the vicarious function must cease. This is evident from a case of Lippman's²³ of acute Addison's disease which lasted only 18 days. The cortex and medulla were found to be destroyed by caseation; an accessory gland was found to be hypertrophied. No tubercle bacilli were demonstrated in the hypertrophied gland. Thus the detoxicating power of the cortex is not only evident *in vitro*, as in the case of cobra venom, but also *in vivo*, as in nephritis and Addison's disease.

The cortex seems to have an effect upon bacteria. The cortical lipoids were found by Elliott²⁴ to have disappeared in all acute febrile diseases, in acute septic conditions and to a lower degree in chronic infections. He claims that cortical lipoids are not influenced by postmortem changes as the epinephrin content in the medulla. It should be emphasized that in the influenza epidemic of 1918 many cases were observed with such pronounced asthenia that they reminded one of Addison's syndrome with an additional fever. In connection with the possible rôle of the cortex in this condition it may be mentioned that Wells²⁵ found pronounced increases of uric acid in the blood of influenzal pneumonias which terminated fatally.

The cortex also controls the body weight. Elliott and Tuckett²⁶ found that the increase in the size of the body is principally due to an increase in the cortical portion. Exceptionally large suprarenals are characteristic of the guinea-pig and are composed almost entirely of cortex. According to the same authors a five-fold increase in weight of the guinea-pig body is accompanied by a twelve-fold increase in weight of the adrenal cortex. The medullary portion practically remaining unchanged. In man cortical overgrowth leads to a premature adolescence. Emaciation and muscular weakness after epinephrectomies runs parallel to the amount of suprarenal tissue removed. That these symptoms in animals after removal of the adrenals are chiefly due to the cortex is evident from the fact that the animals that possess highly developed accessory glands like rats, stand epinephrectomies better than animals like guinea-pigs, which in a great majority of cases, do not possess them. In guinea-pigs after unilateral epinephrectomy, the remaining gland invariably hypertrophies, while in other animals that possess accessory glands, especially in older ones,

the remaining adrenal does not so often hypertrophy.

Still another function of the cortex is the control of the blood pressure, although to a lesser degree than the medulla. Voegtlin and Macht²² succeeded in isolating from the cortex a substance which, on injection into dogs, caused a considerable rise in blood pressure and had an effect like digitalis. In my own unpublished experiments with intravenous injections of cortex I have obtained a rise in blood pressure in all rabbits experimented upon. I also obtained in animals a slight rise in blood pressure with cholin, purified and crystallized by Dr. Bookman from Merk's cholin, which in the impure state lowers blood pressure. It should be noted that the cortex is the richest organ in cholin. Aubertin and Ambard²³ found in seven out of eight cases of contracted kidney with hypertension, hyperplastic and adenomatous changes in the adrenal cortex; in seven cases of nephritis without high blood pressure and twelve other pathological conditions, similar changes in the cortical portion were noted only on one occasion. So high blood pressure may also be due to hyperfunction of the cortex.

To summarize what has been said so far about the cortex: (1) It furnishes raw material to the medulla for elaboration of epinephrin. (2) It regulates the purin metabolism of the body. (3) Because of this function the cortex is also the regulating organ of the physiological pigment metabolism. (4) It probably destroys pathogenic bacteria of the body. (5) The weight of the animals and the development of the musculature depends chiefly upon the cortex. (6) Controls blood pressure to some extent.

It is superfluous to theorize as to whether the cortex presents the store-house for the lipids or is the actual place in which lipoids are formed; the fact remains that hypercholesterinemia is often present in cases of chronic nephritis which are progressing favorably. Henes²⁴ pointed out that a normal or subnormal figure for cholesterol in nephritis points distinctly to a bad prognosis. In individuals afflicted with Addison's disease in which there is a retention of uric acid in the blood, the cholesterol of the serum was found to be low. Dr. Felsen told me that in four cases of Addison's disease there was a hypocholesterinemia. In a case of my own, under observation for the last two months, there is a low cholesterol, low blood sugar, a systolic blood pressure of 85, eosinophilia of 8 per cent., with the cardinal symptoms; emaciation, asthenia, and pigmentation of the skin and of the mucous membranes of the mouth.

Armed with all these facts stated in this paper it is now possible to approach the question of the relation of the cortex to Graves' disease and to myxedema. The purin metabolism is increased in the former condition; decreased in the latter; of course the reverse occurs in regard to the general metabolism in these conditions. Forsbach²⁵ found strikingly small amounts of creatinin in the urine in cases of exophthalmic goiter. The exogenous factor, like the addition of meat extract, was unable to bring about any increase in the creatinin in the urine. Zehner and Falta²⁶ found that the endogenous amount of uric acid eliminated was very small and the exogenous uric acid was almost nil. On the

contrary in myxedema, Magnus-Levy,²⁷ Haushalter and Guerine,²⁸ and Kowalewsky²⁹ found an increase in urates.

The decreased elimination of uric acid in Graves' disease is similar to the disturbed purin metabolism in Addison's disease, though to a lesser extent. The cause is a similar one: insufficient detoxicating power of the cortex. Thus the increased retention of uric acid in exophthalmic goiter cases must frequently lead to hyperpigmentation of the skin, which, according to Falta,²⁷ is present in 50 per cent. and according to Kocher³⁰ in 30 per cent. of the cases. There is no hyperpigmentation in myxedema, because the detoxicating power of the cortex is increased. Thus the difference in the purin metabolism in Graves' disease and myxedema suggests the hypofunction of the cortex in the former condition and the hyperfunction in the latter.

The cholesterol metabolism is decreased in Graves' disease and increased in myxedema. Youchtchenko³¹ found that in thyroidectomized dogs the lipoids in the serum were increased; in experimental hyperthyroidism they diminished.* Weltman³² found in all his cases of myxedema a marked increase in the cholesterol of the blood; in Graves' disease a tendency to be diminished. Rothschild, who was kind enough indeed to give me data of some of his unpublished works on cholesterol, found hypercholesterinemia in six cases of myxedema, and hypocholesterinemia in 25 cases of hyperthyroidism.

Pathology also seems to be in accord with the assumed rôle of the cortex in Graves' disease and myxedema. Hirschlaff, Landau, Pettavel, Mattin, and Rautman³³ found diminished fat and diminished pigment in the adrenal cortex of exophthalmic goiter cases. Elliott³⁴ refers to a woman, aged 28, who suffered from exophthalmic goiter with tachycardia and dyspnea for four months. She had no fever. Her pulse was *ante finem* 180. At necropsy the cortical lipoids were found to have almost vanished. In a case of myxedema cited by Fry³⁵ the autopsy revealed an increase in the thickness of the adrenal cortex with adenomatous formation and vacuolization of the cells. The medulla appeared to be diminished by fibrosis and the chromaffine tissue reduced in amount.

Besides hyperpigmentation which is found in the Addison syndrome and in Graves' disease, there are other symptoms which are common to both conditions. These are loss in weight and asthenia. I have referred elsewhere³⁶ to gastrointestinal disturbances which are alike in these conditions. The emaciation in Addison's disease is due chiefly to failure of the cortex. The tuberculous process in the glands *per se* cannot be responsible for these symptoms inasmuch as they are found in non-tuberculous atrophies of the suprarenals. The symptoms of Addison's disease are not due to changes in the spine, celiac plexus, sympathetic nerves, or in the nerves innervating the suprarenals. Bittorf³⁷ writes that of 25 cases of adrenal atrophies the sympathetic was perfectly normal in 21 cases, 84 per cent.; only slight changes in 3 cases, 12 per cent.; and only in 1 case were severe changes noted. In Addison's

*Herring, in a recent paper (Endocrinology, Vol. IV, No. 4, Serial No. 16, 1920, p. 583), quotes Gley, who found the suprarenals of thyroidectomized rabbits hypertrophied and full of fat.

disease of the tuberculous type, the changes in the sympathics were also rare and insignificant. It seems, therefore, that the emaciation and asthenia in Addison's disease is chiefly due to the failure of the adrenal cortex, and this viewpoint is in accord with the previously mentioned experiments, that emaciation and muscular weakness in animals after epinephrectomies are chiefly due to loss of cortex.

Charcot¹⁶ described a type of myasthenia in Graves' disease which may be quite extensive. He describes the hyperthyroid myasthenia as a "giving way of the legs." Although this form of asthenia manifests itself in severe cases, milder grades of muscular weakness occur in almost all hyperthyroid conditions. Askanazy¹⁷ found marked atrophy of muscle fibers in exophthalmic goiter cases. Dock,¹⁸ speaking of asthenia in Graves' disease says that insufficient attention was paid to Askanazy's important findings.

In myxedematous individuals the obesity is marked; there is no asthenia, rather plumpness and a lack of "pep." The general metabolic rate is increased in hyperthyroidism; decreased in myxedema. Arteriosclerosis is rarely found in individuals afflicted with Addison's disease, according to Bittorf.¹⁹ Kocher²⁰ writes that sclerotic changes in the vessels are rare in Graves' disease. On the other hand, atheroma of the vessels is frequent in myxedema. The emaciation, and muscular weakness in Graves' disease may possibly be due in part to cortical insufficiency; the obesity and absence of myasthenia in myxedema to cortical hyperfunction. Because of the adrenal medullary deficiency in myxedema one would expect to find asthenia here. But the effect of the diminished epinephrin secretion in this condition becomes so overbalanced by the effect of cortical hyperactivity, that the influence of the former disturbance does not manifest itself. This is probably the reason why clear symptoms of adrenal deficiency remain unnoticed to the clinician. Scholz²¹ writes that the mammae in myxedematous women are occasionally unusually large. I have noted in two of my female patients afflicted with Addison's disease atrophy of the mammae. One must consider the mammary enlargement as a sign of cortical hyperfunction similar to those enlargements of the breasts found in girls of 9 or 10 of the early adolescent type which are supposed to be due to cortical overgrowth.

The excellent results, reported by Plumer in a recent paper read before the Eastern Medical Society, obtained in rapidly reducing the swelling of the face by thyroxin in myxedematous individuals, are possibly the result of the reduction of cortical hyperfunction by the drug. That such an assumption is not a speculation becomes evident from Kocher's observations on hyperpigmentation in Graves' disease. Kocher²² states that after surgical procedures in exophthalmic goiter cases, be it ligation or partial thyroidectomy, the brown color of the face in those who are pigmented entirely disappears, and is replaced by a healthy rosy color. The excessive pigmentation in such cases disappears forever, provided suprarenal extract had been administered for some time. Inasmuch as an important symptom like cuticular pigmentation disappears after treatment by suprarenal extract, cortex would serve the purpose better. The medullary part is theoretically

contraindicated in Graves' disease since there is overactivity of the medulla in the latter condition.

Suprarenal treatment also gave good results in individuals afflicted with v. Reclinghausen's disease, which, according to Foà,²³ is a primary atrophy of the suprarenals. Chaffard and Brodin²⁴ report a case which apparently confirms the connection between hemochromatosis and the suprarenals. Suprarenal treatment was followed by immediate and noticeable improvement in Pic's and Jullien's²⁵ cases.

To sum up: Some of the clinical symptoms found in individuals afflicted with Addison's disease, such as emaciation, asthenia, and hyperpigmentation, manifest themselves, truly to a lesser degree, in individuals suffering from Graves' disease. The symptoms have been shown to be due chiefly to various degrees of adrenal cortical deficiency. Because of the mild grade of cortical hypofunction in hyperthyroid states, the above mentioned symptoms are not as frequent or as pronounced as in Addison's syndrome. The hyperpigmentation in Addison's disease, as well as in Graves' disease is due to the same cause, i.e. to the increased retention of uric acid in the blood on account of adrenal cortical insufficiency; since the cortex is not able to bind or oxidize the excessive uric acid which accumulates in the blood, that uric acid is deposited in the skin where through oxidation it turns into pigment. The gain in weight and the absence of true asthenia in myxedema must be due indirectly to hyperfunction of the cortex. Abnormal pigmentation of the skin is absent in myxedema because the elimination of uric acid is increased and the rest which is not eliminated the hyperfunctionating cortex is able to oxidize in its tissue.

Conclusions.—1. There is a hyperfunction of the adrenal medulla in Graves' disease and hypofunction in myxedema.

2. There is a hypofunction of the cortex in Graves' disease and a hyperfunction in myxedema.

3. The proofs are experimental, histological, biological, and clinical.

4. The suggestion follows, therefore, that hyperthyroidism and myxedema are not monoglandular disturbances.

THE VALUE OF VACCINE THERAPY VERSUS TONSILLECTOMY IN SYSTEMIC DISEASE OF TONSILLAR ORIGIN.

By HAROLD HAYS, M.D., F.A.C.S.,

AND

ARTHUR PALMER, A.B., M.D.,

AND

THOMAS S. WINSLOW, B.S., M.D.,

NEW YORK CITY

We desire to present a subject of considerable interest which we believe has heretofore been treated in a more or less haphazard manner. The term focal infection is greatly in the thought of practitioners in all lines of medicine. Every unaccountable disease or peculiar train of symptoms seems to come under this heading, with the result that we are seeking in every nook and cranny of the body for a possible seat of infection. The teeth, the oral cavity, the tonsils, the intestines, the appendix, the gall-bladder, each one separately and sometimes many of them together, have been more or less definitely proved as the etiological factor in a curious and unaccountable train of joint symptoms. And, in their turn, the teeth, the tonsils and the appendix have been removed, the intestines treated, and the gall-bladder opened. When any or all of these operations have not been possible the physician has had to resort to vaccine therapy, with results that vary with the individual doctor and individual patient.

We have no doubt that many physicians are as well acquainted as we are with focal infections. For example, W. H. Haskins reports certain eye diseases in focal infections of the teeth, and Dwyer reports focal infections of the eye from the intestinal tract. We understand that in one of the large clinics of this country, teeth are considered such an important etiological factor that no one who goes there comes away without missing at least one or two molars. What does one mean by the term focal infection? Is the focal infection the cause or the result? In the papers above cited, one author speaks of eye diseases as the result of focal infections of the teeth and the other speaks of focal infections of the eye from the intestines. We are inclined to believe that the original infection is a "local" infection and that the systemic result is a "focal" infection. However, we are not particularly interested in cases other than those of tonsillar origin, and it is our purpose to analyze the cases we have seen in private practice which have been closely studied and to give our conclusions.

In the course of the past few years it has been definitely established that innumerable maladies of heretofore unknown origin spring from a localized

infection, many times the infection being located in the tonsil. That the tonsil can cause systemic trouble is evidenced by the fact that clinical reasoning establishes our conviction that, for example, acute tonsillitis is directly responsible for acute articular rheumatism. Moreover, Wood and others have done experimental work on animals to show the direct relationship of the tonsil to important structures like the lungs. Again, our blood cultures, taken during or right after an attack of acute tonsillitis, have shown the presence of various pathogenic organisms. But one is not content to think that rheumatism is the only disease with which one has to deal. Among important others are endocarditis, kidney disease and iritis. These are more or less dependent on the rheumatic disease but other authors mention pleurisy, acute osteomyelitis, tuberculosis, general sepsis, actinomycosis, chorea, Hodgkin's disease, pericarditis, myocarditis, neuritis, adenitis, keratitis, herpes, phlebitis, scarlet fever and possibly typhoid fever, leukemia, and appendicitis. To these we should like to add a chain of symptoms indefinitely grouped under the terms mental and physical depression.

The normal tonsil may act as a channel while the diseased tonsil acts as a definite focus of infection. Wood shows that the tubercle bacillus may pass through tonsillar tissue into the lymphatics and not cause local disease in the tonsil. He reports 5:2 per cent. tuberculous tonsils in 1,671 cases examined. Anderson has shown by animal experiments that pigments and various microorganisms may be taken up by the tonsils and carried to neighboring lymph nodes. Stohn states that abundant immigration of leucocytes is constantly taking place from the deeper tissues into the oral cavity. The space formed in the epithelial layer often remains open and becomes a convenient door for infected material to enter. Goodale found that carmine readily passes through the hypertrophied tonsil. Packard reports five cases of endocarditis following acute angina, while Elliot states that many toxins and toxalbumins are harbored by the tonsils and diffused into the general circulation.

In our practice it is our custom to take a culture from every nose and throat in which there is evidence of recent inflammation. Cultures from the nose are often sterile, cultures from the nasopharynx show a multiplicity of bacteria. Cultures from the tonsils are taken, both from the surface of the tonsil, from the tonsillar crypts or from the supratonsillar fossa whenever there is any evidence of any tonsillar disease. The disease may not be evident on the first superficial examination. Many times the tonsils cannot be seen until the patient is made to gag, when they present themselves very plainly. It is surprising to note at that time how many of the crypts will open up so that one can see a diseased condition which did not appear before. We do not hesitate to say that there is no way to tell whether a tonsil is responsible for a systemic infection without taking a culture to find out whether pathogenic bacteria are present in sufficient numbers to make us feel that they may be causing the trouble.

Cultures have been taken in over a hundred cases which form the basis of this report. At first the culture was taken after cleaning off the surface of

the tonsils with some warm, mild, alkaline solution. The mouths of the crypts were sought and the swab applied to those parts if possible. It is surprising to note in how many cases the mouths of the crypts are so small that no culture can be taken from them; in a few instances, no cryptal openings could be found. In these cases, cultures were taken from the surface of the tonsils or from the supratonsillar fossa. It is in the cases with small cryptal openings or no openings at all that one finds bacteria accountable for systemic disease. This is not difficult to explain when one considers the pathology of acute tonsillitis. One of us (Hays) explained this pathology some years ago. In acute tonsillitis the openings of the crypts are considerably swollen and constricted with the result that minute pus pockets are formed in the body of the tonsil. Systemic disease results from the chronicity of such a process, the result being that, as the infectious matter cannot escape externally, it finds its way into the system. As a rule, where crypts are wide open, systemic disease does not result unless the drainage has met with an obstruction somewhere.

During the past few months we have been taking our cultures from the supratonsillar fossa. The results have been most gratifying. When cultures are taken from the surface of the tonsils or from the superficial portions of the crypts, one gets a multiplicity of organisms and it is often difficult to tell which predominates. On the other hand, cultures taken from the deeper portion of the supratonsillar fossa show one organism in pure culture. We are in the habit of taking cultures from both supratonsillar fossæ and invariably the same organisms are found on both sides. In one of our cases, we found a pure culture of the influenza bacillus. We recall one case of persistent iritis of over a year's duration in which the tonsils could not be seen except during the act of swallowing and where there was no evidence of cryptal disease. A culture taken from the surface of the tonsils showed a streptococcus viridans and staphylococcus aureus. The tonsils were removed about one year ago, since which time the iritis has entirely disappeared and the patient's general health has improved considerably. We have seen many tonsils in which the mouths of the crypts have been filled with cheesy material where there is no evidence of systemic disease and we have come to the conclusion that the tonsil which drains well—in other words where there is no occlusion of the crypt—is not nearly as dangerous as the tonsil which on the surface frequently shows no evidence of disease. In other words, the amount of systemic infection seems more important to us than the size of the tonsil or its surface condition. There is one diagnostic point of great importance. If the tonsillar gland, beneath the angle of the jaw, is enlarged or tender, it is apparent that there is tonsillar disease which should be attended to at once.

Our throat cultures, whether taken from the crypts or from the tonsillar surface or the supratonsillar fossa, have shown a variety of bacteria. Among those found most frequently have been the streptococcus—chain, hemolytic, pleomorphic, viridans—staphylococcus, pneumococcus, micrococcus tetragenous, micrococcus catarrhalis, pseudo-influenza bacillus, influenza bacillus, diphtheroids, un-

determined diphtheroids and other unidentified organisms. We have purposely not mentioned the Conellan-King diplococcus for we do not believe we are in a position to say definitely that there is such an organism. Bacteria, so classified, were present in the first cultures taken by us when the bacteriological work was done by a laboratory to which Dr. King sent a great many of his cultures, but since the work has been done in our own laboratory by Dr. Winslow, we have not found an organism such as Conellan and King describe.

We consider that the streptococci, mainly the streptococcus hemolyticus and viridans, are the only pathogenic organisms in the throat which are responsible for systemic infection. There may be exceptions to this statement but we are yet to see the first case in which this organism does not predominate in the throat in association with, for example, rheumatic diathesis. The patient may not be aware of any throat ailment and an antecedent tonsillitis may have occurred so long ago that the patient may have forgotten that he had the disease. One may properly ask here: "If, as you state, the worst cases of systemic disease associated with diseased tonsils occur when the crypts are so tightly closed that sometimes it is impossible to get a culture from them, how can you determine that a culture taken from the surface of supratonsillar fossa is of any value? Do not these same organisms occur in any throat?" We support our case on the clinical evidence. Normal throats do contain many organisms but it is seldom that the predominating organism is a streptococcus unless there is some diseased condition which needs remedying. We have frequently heard the statement made that a streptococcus, particularly the streptococcus viridans or hemolyticus, can readily be recovered from any normal tonsil and therefore its recovery is no evidence that it is the cause of systemic disease. Our experience makes us feel otherwise. In the majority of our cases, other organisms have been isolated—organisms which we have not considered pathogenic. Where we have found a streptococcus in the tonsils associated with systemic disease, the removal of the tonsils or administration of vaccines have been invariably followed by good results. Again, although it may be impossible to find an opening of a crypt large enough to admit a platinum loop or a sterile applicator, the opening may be large enough to allow of the escape of a certain number of bacteria, not in sufficient numbers, however, to eliminate the main focus of infection.

All our vaccines were made up of the strength of 500 million bacteria to the cubic centimeter. The injections were given intradermally. The first dose was a half c. c., and every third day after that a full c. c. was administered, until ten doses in all were given. We seldom saw any severe systemic reactions like one sees after the administration of typhoid vaccine. Local reactions of a mild type were often present.

We shall not attempt to outline every step in the procedure of preparing the vaccines but merely emphasize a few points of importance. First of all the vaccines were made with the aim always in view of obtaining the organism in its most virulent and active form. To accomplish this result care was taken to make as few transplants as necessary, and

to subject it to as little heat as possible in sterilizing.

To make as few transplants as necessary only blood agar plates were used and the bacteria scraped off dry into the saline. Some consider it poor technique to use blood agar media for the final growth. But we found if the organisms were scraped off dry rather than washed off there was no discoloration of the saline from dissolved or hemolyzed blood. In doing this there was one difficulty. Certain strains of streptococci, owing to the richness of the media, have a tendency to invade the media rather than grow on its surface. This makes it most difficult to obtain enough of the organisms by dry scraping. This can be overcome, however, if the plate is thickly seeded and incubated for only ten to eighteen hours. The young colonies will not have become set by that time and the growth will generally be sufficient and easily scraped off. The blood agar plates were made from guinea-pigs' blood and the agar was titrated as near the neutral point as phenolphthalein would allow.

The next important step in obtaining virulent organisms was in the sterilization. If a vaccine is made under proper sterile care no spores will be present, hence no need for more than one sterilization. Our vaccines were never sterilized but once and at a temperature varying from 58 to 60 degrees. This was continued for an hour in a concentration of 0.8 per cent. phenol. Only once in over a hundred cases was the control found positive. But as there is a very small margin of safety in this method it is necessary to use a generous amount of the vaccine in making the control. We have never experienced any bad result in using the phenol in the strong percentage above mentioned.

A few words as to the method of counting the bacteria may not be out of place here. The old way of counting against blood cells seemed both too inaccurate and too laborious. We therefore made up several standard dilutions with Hopkins tubes. Using these as comparisons, we made the new vaccines to match. However, several types of standards were necessary. A dilution of 500 million of *B. coli* per cubic centimeter does not match the same dilution of catarrhalis or streptococci, due to the fact that one mixes in an even homogenous suspension while the other appears flaky. This difficulty was met by having a standard dilution of typhoid which would sufficiently match *B. coli*, pneumococci, influenza staphylococci, and the diphtheroids. Then a second standard was used to match the streptococci and catarrhalis and chromogenic diplococci. This made counting a much simpler procedure and we feel that it was the most accurate method.

Vaccine treatment for disease of tonsillar origin is of comparatively recent development and no very large number of cases are reported in the literature. Howland and Hoobler consider the subject from the point of view of the type of organism. They found that a localized infection caused by the *staphylococcus aureus* was cleared up with four to five inoculations and three cases of general septicemia, due to the same organism, recovered. Local streptococcus infections were helped but responded less rapidly while some showed no improvement after prolonged treatment. No apparent benefit re-

sulted when the pneumococcus was the cause, while a few cases of unusual infection were helped. Dabney thinks that vaccines abbreviate convalescence and cites three cases of acute tonsillitis, one with abscess formation, improved by one or two doses of vaccine, while four cases of arthritis due to tonsillitis infection were cured. Stone considers that success in vaccine therapy requires (1) localization of the infection and (2) a predominating type of organism. He states that vaccines cannot be used promiscuously, that they are of value in prophylaxis but no cure-all for disease. The best results were obtained in staphylococcus infection. Miller and Lusk claim that vaccines are non-specific in therapeutics because the same results may be obtained by the injection of proteose and albumose. Regardless of the possible good results from the use of vaccines which we have seen stated by others, we do not hesitate to say that in no instance should vaccines be given with the promise of a relief of symptoms where it is possible to do a thorough tonsillectomy. On the other hand, the removal of the tonsils will give an absolute cure—that is if the tonsils are the sole cause of the trouble; the administration of vaccines may merely temporarily relieve the trouble, always leaving a certain amount of diseased tissue *in situ*. We have administered vaccines for systemic disease of supposed tonsillar origin in over seventy-five cases, and in few instances have we completely satisfied ourselves that the vaccines have caused the systemic disease to disappear.

In view of the facts stated above, one may ask whether we sincerely believe that vaccines are ever of any value in systemic disease of tonsillar origin. There are certain patients to whom vaccines must be given for there are contraindications to operation. Among such patients are those whom we consider above the operative age. It is only fair to try vaccines first in patients over fifty years of age. We consider tonsil operations on patients over that age unjustifiable until vaccines have been used, unless the systemic disease is so severe that no other remedy will suffice. And we are most happy to say that our most successful results in the treatment of systemic disease of tonsillar origin by vaccines have been in elderly people. We have in mind half a dozen cases of subacute arthritis which have been relieved for over a year and perhaps have been permanently cured by this method of treatment. Then there are certain conditions of the patient, such as a severe kidney lesion, which make it imperative to administer vaccines first. We do not consider the milder forms of endocarditis a contraindication to operation. Severe valvular lesions should be treated with vaccines first although we have seldom any good results in these cases. It is possible, however, to tone up the system in this way so that the patient's resistance may be increased. There is another class of cases in which vaccines must be used—that is in patients who simply will not submit to operation. We have no alternative in the matter and often, after the patient sees that the vaccines do little or no good, he is more amenable to our common-sense advice.

Do we consider tonsillectomy a curative measure in systemic disease of tonsillar origin? Upon this question there is considerable difference of opinion.

The reason for this difference is not difficult to understand. Tonsillectomy has been followed both by brilliant cures and by unforeseen disaster. Certainly the good results far outnumber the bad, yet Stucky reminds us that in a series of cases he found one case of facial paralysis lasting five weeks; three cases of marked impairment of the voice; two cases of marked cicatricial contracture of the pillars of the tonsil, resulting in discomfort in swallowing; three cases of uvula removed; two cases of loss of tone of the tensor palati and levator palati muscles, causing regurgitation through the nares; one fatal hemorrhage; nine cases of secondary hemorrhage, and two of cellulitis. Further, Sheedy reports that in fifty cases of tonsillectomy which he studied, 80 per cent. had some throat deformity two to three months after operation. Seventeen had speech defects for three weeks, two lost their singing voice, while the voices of thirteen were improved. Faulty technique was responsible for many of these bad results.

Good results in the ordinary case are the rule, providing the operation has been complete and in the great majority of cases the local and general condition of the patient is much improved after diseased tonsils have been removed. Of the unusual cases Dabney reports three cases of chorioretinitis, two cases of multiple arthritis with Bright's disease, cured, and one case of Darier-Roussy sarcoid disease improved by tonsillectomy. He also cites four cases of endocarditis of proved tonsillar origin which died and might have been saved if a tonsillectomy had been performed. Beck states that the tonsils are the focus of infection in 20 per cent. of chronic infections due to focal disease and in 30 per cent. cure takes place after complete tonsillectomy. The patient's resistance to other diseases is increased as well, by the improvement in the general health.

The vital question is, which cases to operate and which to leave alone. Swain finds French's method of determining the pathological tonsil useful. A light is passed behind the tonsil *in situ* and thus the structure can be more easily examined. He does not consider cheesy crypts a criterion for operation, as all tonsils at one time or another have some white matter in the crypts. Swain states that we cannot consider the tonsils merely an irresponsible functionless lump of matter but as an organ which if not doing its full physiological duty or if distressed can modify some of the most vital functions of the blood and lymph. The tonsils are intimate parts of the lymphatic nodes of the body and cases of general lymphatic enlargement always involve the tonsils. We must not remove tonsils indiscriminately nor must we leave them alone entirely. We must operate thoroughly but must remember that we do not give immunity by operation in all cases.

We feel that vaccine therapy is still in its infancy and that the future may show us that autogenous vaccines may take the place of a radical operation. This is not so at the present time. Yet we have enough confidence in vaccines to have them made up in every case where we suspect that the systemic disease may be of tonsillar origin. This is done for two reasons. In the first place, the patient may object to operation and the vaccine must

be used, and in the second place, sometimes even when the tonsil is radically removed, some focus of infection remains which can be eradicated by the administration of a few doses of the vaccine.

In closing we should like to emphasize the following points:

1. Systemic disease is often of tonsillar origin even when the tonsils are small and show little evidence of disease.

2. Cultures from the tonsils should be taken in all cases of systemic disease.

3. Cultures taken from the tonsils, preferably from the supratonsillar fossa, showing any form of streptococcus, should be considered prima facie evidence of tonsillar disease sufficient for their removal, if associated with systemic disease.

4. Tonsillectomy is a better procedure than the administration of vaccines unless operation is contraindicated.

5. A poorly performed operation is no criterion of the value of tonsillectomy. A small piece of tonsil remaining may still keep up the systemic infection.

6. The value of the vaccine as a curative agent is yet to be proved.

2178 BROADWAY.

THE WHITMAN OPERATION AS APPLIED TO VARIOUS TYPES OF PARALYTIC DEFORMITIES OF THE FOOT.

RESULTS IN THE AVERAGE CASE.*

By ARMITAGE WHITMAN, M.D., F.A.C.S.

NEW YORK.

The Whitman operation, consisting of astragalectomy and backward displacement of the foot, has been in use at the Hospital for the Ruptured and Crippled since 1897. Up to January 1, 1920, 920 such operations had been performed. During the last five years the yearly average has been 100 such operations. It is, therefore, evident that in this institution the faith in its efficacy has steadily increased, and that it is now regarded as a standard procedure.

In an interesting paper entitled "Removal of the Astragalus in Paralytic Feet," Dr. J. W. Sever† says: "It has always seemed to me wise and of distinct value to present end results from clinics or individual operators, regardless of the nature of the results." Following this preface he then reports the results of the Whitman operation as performed at the Children's Hospital, Boston, observed in a series of 217 feet. Upon Dr. Sever's suggestion I wish to comment upon the methods of and the results obtained by a similar research recently conducted at the Hospital for the Ruptured and Crippled. I think the methods employed are of even more importance than the results obtained, as if we ever are to overcome the force of institutional, local, or personal prejudice and arrive at conclusions of scientific value, we must have a common ground from which to start, and similar methods to pursue. In reporting the results of any operation, and judging thereby of its success or failure as a standard procedure, it is essential to have a definite

*From the Hospital for the Ruptured and Crippled, service of Dr. Royal Whitman.

†Sever, J. W.: *Journal A. M. A.*, lxx, 18.

idea of why the operation was performed and what were the results expected from it.

I recently investigated a series of 60 cases from Dr. Royal Whitman's service in which the Whitman operation had been performed, with the aim of getting as accurate information as possible as to its results in the average case. To this end the record clerk took the names of ten patients operated on in 1915, ten in 1916, ten in 1917, ten in 1918, and 20 in 1919. (It was my original intention to analyze 100 cases but lack of time forced me to stop at 60.) The names were taken in order as they appeared upon the operating book. If Case I could not be traced, Case XI was substituted, and so on. The possibility of favorable selection, as to either class of case or results was thus obviated.

FIGURE 1.—Card used for summarizing cases. LA, distance from anterior superior spine to tip of internal malleolus; LH, distance from anterior superior spine to heel.

When the patient appeared at the clinic, his hospital record was investigated, and his past and present condition recorded on a card as shown in Fig. 1. Fig. 2 shows a form of questionnaire sent to patients living at a distance, who could not return, to get a general idea of their condition.

Name: R——, H——.
Address: Box 38, Brownsville, Jefferson County, N. Y.

Age: 13
What is the date of your operation (astragalectomy)? May 16, 1918.

Do you limp? No.

Do you walk without any apparatus? No.

Do you walk with a brace? Yes.

Do you walk with a brace or crutches? Yes; both.

Do you walk at all? Yes.

Before the operation did you walk without apparatus? No.

Before the operation did you walk with a brace? No.

Before the operation did you walk with a brace or crutches? No.

Before the operation did you walk at all? No.

Was your foot deformed (twisted out of shape) before the operation? Yes.

Has the deformity been improved? Yes.

Is any deformity still present? No.

What is your present occupation? School student.

Do you consider the operation a success? Yes.

If not a success, why? (for example, because the foot is still deformed, weak or still painful?)

Have you noticed any increase of power in the muscles of your foot since the operation? No.

How much shorter is the operated leg? Not any.

If you are not satisfied with your present condition, what would you like to have done for you? I am satisfied.

FIGURE 2.—Form sent to patients living at a distance.

The operation was done for three conditions: (1) For calcaneus, or perhaps it would be more strictly accurate to say for disability, of which the most important feature was paralysis of the calf muscle, thus embracing calcaneovarus, calcaneovalgus, etc. (2) For dangle feet. (3) For lateral deformity.

The object of the operation varies in each group. In the first it is, by checking dorsal flexion at a right angle, to restore propulsive power to the foot;

secondarily to restore symmetry and thus improve the appearance of the limb; finally in young and recently paralyzed cases by forcing functional use to check the extreme atrophy of the fore foot.

In the second we intend to give the foot propulsive power and to do away altogether with lateral instability. In the most severely paralyzed cases the operation has been done simply to permit brace wearing with comfort, doing away with the pressure sores so frequently encountered as the result of a flail ankle wabbling and chafing against the up-rights of the brace. In the third group the object is to check, by removing the possibility of lateral motion at the subastragaloid articulation, a progressive varus or valgus deformity that already has not been, or does not seem likely to be amenable to other measures such as tendon transplantation.

Briefly, then, the operation was performed for calcaneus, for dangle foot, and for lateral deformity, and the objects sought primarily in the various groups were, correspondingly propulsive power, stability, and arrest of deformity.

The conditions upon which the results were classified were: (1) That dorsal flexion should be checked at a right angle. (2) That there should be no appreciable lateral deformity when weight was borne. (3) That apparatus when worn should be worn with comfort. (4) That the patient's opinion of the result should be satisfactory. The results were accordingly classified as Satisfactory, Improved, Poor.

TABLE II.

- (1) Florence C. Case 43. Operated, June 23, 1919; left calcaneus, slight tendency to varus; has had no after-treatment whatever, owing to bad home conditions.
- (2) Richard G. Case 49. Operated, June 23, 1919; calcaneus; dorsal flexion checked at 80°; insufficient backward displacement.
- (3) Mary Mc. Case 53. Operated, May 19, 1919; right valgus, secondary operation; dorsal flexion checked at 80°; still has considerable valgus deformity.
- (4) Gladys B. Case 31. Dangle foot in equinovarus, operated June 24, 1918; had a resistant equinus deformity, operation a failure; has had no postoperative supervision.
- (5) Catharine C. Case 35. Right varus deformity, operated Sept. 9, 1918; still has varus deformity, due to slight power in the tibialis anticus and posticus; should have a supplementary tendon transplantation.
- (6) Nathan R. Case 39. Right calcaneus, operated Jan. 21, 1918; has dorsal flexion to 45° in spite of good backward displacement of the foot; result classed as unsatisfactory, though the patient prefers his present state to that before operation.
- (7) Martin D. Case 22. Dangle foot, operated Oct. 29, 1917; slight valgus and insufficient backward displacement of the foot, though dorsal flexion is checked at a right angle.
- (8) Minnie S. Case 26. Left dangle foot in equinus, operated March 31, 1917; very slight tendency to varus, not quite sufficient backward displacement.
- (9) Annie L. Case 16. Left calcaneovarus, operated 1916; dorsal flexion limited at 80°; insufficient backward displacement.

There is always in every case, and this should be thoroughly understood, a tendency to the eventual development of varus deformity because of the removal of the support afforded to the scaphoid, by the head of the astragalus, thus shortening the inner border of the foot. This deformity, however, takes place at the mediatarsal joint, and is, properly speaking, an inward deviation of the forefoot. This tendency is always increased by the persistence of the toe flexors, which Dr. Sever mentions. On this account it is our practice to instruct the patients in

W-Whitman.
O-Other
S-Satisfactory
I-Improved
F-Failure

Table I classifies the conditions for which the operation was done and the results. Twenty-eight were operated by Dr. Whitman himself, 32 by surgeons on his service. Eighty-five per cent. of the results were successful; 65 per cent. of the patients wearing apparatus were enabled to discard it. One patient regarded the operation as a failure; 90 per cent. were satisfied with its result.

Table II is an analysis of the unsatisfactory results. It will thus be seen that the most frequent cause of failure is insufficient backward displacement of the foot, which is accepted as *prima facie* evidence that the operation was improperly performed. Next would come varus or valgus in dangle feet from the pull of some muscle of apparently inconsiderable power.

daily manipulations of the foot to guard against the development of this deformity.

There are such striking discrepancies between the operative results of the Children's Hospital and our own that it might be well to examine thoroughly the possible causes, particularly because there seems to be a widespread impression in Boston and elsewhere, that the operation leads to ankylosis at the ankle joint. There are even some misinformed to such a degree as to believe that one of the objects of the operation is to produce ankylosis between the tibia and the os calcis. The general looseness of the ideas prevailing in regard to the operation is largely due to the unfortunate prevalence of the appellation "astragalectomy," an error into which even Dr. Sever falls in his title "Removal of the

Astragalus in Paralytic Feet." In fact, the removal of the astragalus is primary, it is true, but the keystone of the operation is the backward displacement of the foot. One must bear in mind the original purpose of the operation and be continually conscious of the fact that its application to the treatment of any deformity other than talipes calcaneus is at the responsibility of the operator, who should be clear in his own mind as to just what he expects to gain by the operative procedure. For example: What may be expected from the application of an operation designed to remedy the deformity of calcaneus to 91 cases of the equinus type is not clear. (Table I, Dr. Sever's article.) The essential feature of the operation is backward displacement of the foot, which by actual bony contact between the scaphoid and the tibia checks dorsal flexion at a right angle, and thereby endows a functionally passive foot with resistance. This is the essential feature of the operation in the condition for which it was originally designed, and strangely enough it is not even mentioned in Dr. Sever's article, unless we may assume that it is included under the somewhat vague heading "functionally better" (Table V). The writer also speaks of inserting the peroneals into the os calcis after Whitman's method. As Dr. Whitman has not employed this method for the past ten years at least, either transplanting the peronei into the tendo Achillis or leaving them undisturbed, and as some of the eight operators mentioned find it necessary to remove the astragalus in two parts, I conclude that a standard technique is not a feature of the cases reported in this series. The advantages of removing the bone as a whole are indicated by an illustration from Dr. Sever's article, an x-ray picture which he employed to show bad postoperative position in which a large fragment of the astragalus remained in situ. I therefore quote the description of the operation from Dr. Whitman's text book on Orthopaedic Surgery,* as we must agree that in reporting end results the means employed to accomplish them should be, at least, approximately the same.

Description of Operation.—The line of incision begins at a point about an inch above the extremity of the external malleolus midway between it and the tendo Achillis, and is continued downward and forward about three-quarters of an inch below the malleolus over the dorsum of the foot to the external surface of the head of the astragalus.

The sheaths of the peronei tendons are opened and the tendons are cut below the malleolus and drawn backward. The bands of the external lateral and interosseous ligaments are divided and the head of the astragalus is freed from its attachments to the tibia and scaphoid. An elevator is then inserted between it and the os calcis, and, the foot being forcibly inverted, the head of the astragalus is drawn from the wound, and, the attachments on its inner and posterior borders having been cut or broken, it is removed.

One then prepares the new articulations. A thin section of bone is cut from each of the adjoining surfaces of the cuboid and os calcis, and turned backward to form a flap. On the inner side a knife

is passed about the superior and internal surface of the scaphoid and the tissues are separated by an elevator. The foot is then displaced outward and the malleoli are laid bare by dissection from their ligamentous attachments and are reshaped somewhat on their internal surfaces to fit the new articulations. The peronei tendons, freed from the lower extremity of the fibula, are passed through a slit at the base of the tendo Achillis, sewn firmly to it, and then drawn forward and reunited to their distal extremities to serve as ligaments.

The foot is now displaced backward, the external malleolus covers the calcaneocuboid articulation, the internal overlaps the navicular. The above-mentioned flap is turned upward and sutured to the external malleolus by a mattress suture of chronic gut. The wound is then closed with catgut sutures and the foot is fixed by a plaster splint in an attitude of moderate plantar flexion and abduction.

In the routine of hospital practice the operation is performed under the Esmarch bandage. The tendons are sutured with kangaroo tendon. The wound, having been cleansed with warm saline solution, is closed without drainage. The foot and leg are bandaged with sterilized sheet wadding, over which a light plaster is applied, holding the foot in the attitude described, and the leg at a right angle to the thigh. The limb is afterward suspended between tapes running from the head to the foot of the bed. Great care is taken to avoid constriction. To this, and to the rest assured by the plaster splint, is ascribed the very slight discomfort following the operation, and the absence of complications.

The after treatment is also deserving of consideration. At the Hospital for the Ruptured and Crippled it is our routine to place the foot immediately after completing the operation in an attitude of moderate plantar flexion and abduction, in which it is maintained by plaster of paris. The leg is flexed at anywhere from a right angle to 135° on the thigh. In this attitude it is suspended by tapes or other apparatus for the purpose. At the end of about three weeks this splint is removed and the walking plaster is substituted, which extends to the knee and holds the foot in moderate equinovarus, the sole being levelled by a cork wedge. Dangle feet are placed at a right angle. The patient is encouraged to walk with even steps and to bear weight on the forward part of the foot. After two to four months the new joint will have become stable and the fixed support may be discarded for a shoe with a cork wedge beneath the heel of sufficient thickness to compensate for whatever was the pre-existing shortening. If necessary the other border of the shoe is raised to counteract the tendency to varus deformity. The parents are instructed in the daily manipulations which are sometimes necessary, and always advisable, to guard against this tendency.

I again emphasize that ankylosis at the ankle joint is neither sought for nor expected, and except in flail extremities is regarded as an exceedingly unfortunate result. It was not found in any of the 60 cases examined in this series. It would seem unnecessary to insist upon this point save for the fact that other authors than Dr. Sever have fallen into this misconception. Dr. Lovett says, "Although it

*Whitman: Orthopaedic Surgery, Lea & Febiger, Edition 6.

*Lovett, R. W.: Treatment of Infantile Paralysis, P. Blakiston's Son & Co. Second edition, page 118.

would seem that a sufficiently destructive removal of joint surfaces would surely result in ankylosis, the fact remains that skillful and experienced surgeons will *occasionally* (the italics are mine) fail to secure a stiff joint.* Again, "Because in the modified operation as performed at the Children's Hospital, Boston, an ankylosed ankle is not aimed at."

As a result of the analysis of these cases I agree with Dr. Sever that astragalectomy is not an operation to be advised for any foot showing lateral instability as the result of the paralysis of one muscle group alone. I agree with him that it is as good an operation as any on feet which are flail, or those which have only one muscle group left, although I should be interested to know what procedure he considers equally effective. I agree with him that "In feet in which there was good muscle power before the operation and good weight-bearing position of the foot" the operation should never have been performed. I diametrically disagree with him when he says that "it is not an operation that will cure a limp or even improve one as a rule." Selected cases may be shown in which the characteristic hamstrung gait of calcaneus has been altered to one, the irregularity of which to the average person would be imperceptible. I agree with him that it is not "an operation to be advised lightly or universally for foot deformities."

The results of the two series are so extraordinarily at variance that I cannot but conclude, hesitate as one must to do so, that the results expected, the methods employed, and the standards of criticism, must be equally apart. How, for example, as reported in Table V, 80 cases out of 217 show "good lateral movements" is difficult to understand. One would like to know, after the removal of the subastragaloid articulation, where such lateral movement took place.

I conclude that the fundamental reason for the divergent opinions lies in the selection of cases judged suitable for the operation. Widely as the field of a useful operation may be expanded, when its original purpose was to remedy the disability following paralysis of the calf muscle, its application to 69 cases in which the gastrocnemius was classified as "good to fair," would seem, to say the least, hyperenthusiastic.

The results of Dr. Sever's investigation are interesting and instructive. I am confident that a better selection of cases and a more standard operative technique will make the results of his next series more encouraging.*

*A detailed report of the cases upon which this paper is based, and a fuller discussion of the principles and practise of the operation, will be found in an article entitled "Astragalectomy and Backward Displacement of the Foot—an Analysis of Its Practical Results," read before the American Orthopaedic Association at its last meeting.

233 LEXINGTON AVENUE.

Cocainism in Berlin.—The nervous strain caused by the war has left the people in a condition ripe for drug addiction. The abuse of cocaine especially has become widespread in Berlin. The drug can readily be obtained, even in large quantities, not only from druggists but from hotel servants and waiters, prostitutes, etc. These irregular dealers are apt to falsify the alkaloid with boric acid.—*Deutsche medizinische Wochenschrift*.

MAN AND THE ENDOCRINES.

WITH STRESS ON THE FEMALE.*

By G. K. DICKINSON, M.D., F.A.C.S.,

JERSEY CITY, N. J.

BURIED in the earth of Western Europe for over fifty thousand years lay the remains of primitive man, which, when exhumed, were still in good condition. It is claimed they dated from the period just before the last Ice Age. Being intact, those competent to judge report that the bones were big, the lines of attachment of muscle prominent, the joints large, and from close study conclude that he was not tall, but strong, vigorous, and well adapted for the fight necessary for food and protection, and in appearance somewhat approached the anthropoids.

There were five races: four of them more muscular, heavier, and more cumbersome in body than the fifth. This latter, the Cro-Magnon, on account of greater agility (being more slender and lighter), survived where the four perished, and it is supposed that the present race of man descended from this.

If we study the different nationalities, particularly those from mid-Europe, we will find a type which we are compelled to consider as more closely allied to this primitive state. They have large bones, big joints, plenty of muscle, big chests, wide costal margins, and broad abdomens. Their hands and feet are large, the hair coarse and shaggy, the hair margin on the forehead broad, and the eyebrows heavy, meeting over the nose and laterally coming down to meet the hair descending from the scalp. They are hirsute all over the body, particularly on the chest and over the sacrum. There is apt to be a fatty prominence at the lower cervical region. The upper jaw is broad with well set, large teeth, there being an interval between the two incisors, and the second incisor often simulating a tusk. The lower jaw is equally well formed.

This anatomical condition being free from nasal defects, leads to good inspiration and well inflated lungs. The abdomen shows an absence of any defect such as imperfect rotation of colon and visceroptosis. They are of those who were brought up in the open. For many generations both men and women worked on the soil. The women were beasts of burden. Even to-day in some countries we see them doing the heaviest work in the field. They were considered of secondary importance and carried the burden with men as their overlords. These people are hypophyseal; the hypophysis in its secretion stimulating all the tissues mentioned and their activity reacting on the hypophysis to stimulate it.

But, as specialization in life, so-called civilization, advanced, when woman came out of the field and remained in the home, when man took the burden, where culture and education predominated, there resulted a lessened call on the hypophysis, its effect on stimulating growth diminished, and the adrenal, which has charge of energy, became more effective. In people of the adrenal type we have smaller bones and muscle, narrow chests, soft, silky straight hair, a sharp hairline on the forehead, an empty space between the eyebrows, which do not extend far

*Read before the Academy of Medicine of Northern New Jersey, held in Newark, October, 1920.

laterally. There is less hair on the body. Being deprived of the full stimulation of the hypophysis, there is greater tendency to defects of development and malformations of both bone and viscera. The upper jaw is prone to be narrow, with a vaulted arch, deviated septum, teeth small, and not so well placed, the chest flatter, the costal margin narrow, and congenital visceroptosis common, together with malformations in the intestinal tract, failure in development of the large gut, mobile colon, dragging cecum, early recession of the appendix, vagotonia, and all the stigmata of imperfect development making for our high-grade defectives and physiological hermaphrodites.

But modifications do occur, largely influenced by climate and diet. In countries where the diet is principally carbohydrate, disturbances due to developmental defects are not as noticeable as in those where high proteins are mainly used.

So much for the anthropological.

Now from the biological viewpoint. For development, sustenance, and protection in the lowest forms of animal life (where there is an arrangement of cells and some fluid content without a nerve system) there exists a hormone, which activates and correlates the several functions. Injuries are also repaired through its influence.

Somewhat higher in life, we find that which is analogous to our vegetative nervous system. It is autonomic, but with it are associated glands which secrete hormones to aid in the functions of circulation, digestion, reproduction, and protection.

Higher still, we come to the cerebrospinal system, which is a late accessory. The vegetative nervous system is fully developed and the several endocrine glands functionate actively, so that man today is cared for by his internal secretions, his autonomic system, and his mentality as expressed through the cerebrospinal. He is an inclusive trinity.

The endocrines are subject to few pathological processes, except through what might be termed the "sins of man." In a man living a normal life, a life approaching the primitive, little pathology occurs to them, but a man living the modern artificial life, far removed from that which was the custom for hundreds of centuries, suffers thereby. The main disturbances of the endocrines are those of function and have a very severe effect upon the constitution.

The autonomic nervous system is more easily affected, being more recent in development. It is disturbed by climate, diet, and mode of life. But even these are not considerable when the nervous system has inherited full growth and vigor. We seldom see what we nowadays call vagotonia in those who are fully hypophyseal in build and physiology. It is more commonly discovered in the adrenal type associated with defective development: the flat chested, the small boned, those with narrow costal margins and visceroptosis. The perverts, morphological and physiological, are the ones who go to make up our so-called neurotics.

Most neurotic pains are preceded by exhaustion of the sympathetic plexus, the stigma of a chronic rather than an acute process. Types of regional neuritis, neuroses, and a neurotic mind are generally associated with lesions of the sclerotic type, where we have vague expression and mental obsession.

With a life in the open, a life of work, a life of energy, one that stimulates bone, muscle, and gland function, where the only thing taken to inebriate is pure oxygen, we rarely find defective physiology. But in those who for generations have lived in close rooms, have had exercise but spasmodically, who are not earners of their bread by sweat, who are given to lives of leisure, laziness, and intoxication of the toxic type, morbid physiology and a whole vocabulary of symptoms develop. In people who work for a living, who cannot consider their comfort and convenience, whose skin is ever moist, we seldom find a neurosis.

The cerebrospinal system is of the latest development and yet has been the object of study for the longest period. Man's consciousness of himself has led to speculations, diverse theories, and largely unwarrantable conclusions. What this system is anatomically we know pretty well, but what it is physiologically and psychologically we are far from comprehending. To a considerable extent the mind has an influence over the body, though, fortunately, it has none over the sympathetic nor the endocrines. In fact, they are the masters of the mind. Many types of cerebration are practically independent, but character, that is our personality, is dependent upon the endocrines and the autonomic.

With the thyroid juice we are able to metabolize; with the adrenal we give energy to our metabolism; from the liver we obtain glycogen and a something yet unknown to feed the tissue cells of the body and brain and keep their output, be it mental, motor, sensory, or otherwise, at their maximum. It is not inaccurate to say that active mental processes are dependent upon the thyroid, adrenal, and liver, particularly the latter.

But the hypophysis and adrenal are what might be termed "cold" organs. They stimulate for energy. The thyroid and the ovary develop gentleness. They are "warm." The hypophysis and adrenal contract the bloodvessels and raise tension. The thyroid and ovary dilate. We fight with the aid of our adrenals and high tension. We worship, make love, and sympathize through the thyroid, and, in the female, the ovary.

We find that the hypophyseal infect less readily (especially is this true as to tuberculosis), but tend more to tumor formations, while the adrenal type is more susceptible and less resistant to chronicity.

In every gonad there are to be found elements of the other sex, so that a woman may demonstrate male characteristics. Sometimes they are evident anatomically, more often physiologically. When there is a physiological demonstration, there is prone to be soubrette voice, hirsuteness, and sterility. So far as our observations go, the hypophyseal demonstrates this more frequently than the adrenal type.

The endometrium is acted upon by the internal secretion of the ovary, with the resulting production of a periodic menstruation. This is correlated with a temporary enlargement and activation of the thyroid. The hypophysis is also said to enlarge, and through it we have increased tonic and intermittent contractions of the uterus.

If an ovum should be implanted in the endometrium the hypophysis tends to expel, the thyroid preventing, until such time as the ovarian secretion

has enabled the ovum to obtain a placenta. The placenta being formed, it also develops a hormone which passes to the mammary gland, stimulating its growth, eventually with the production of the colostrum. The hormone in the colostrum is absorbed into the general circulation and has an effect similar to that of the pituitary, so that when the tenth oestrus cycle comes around, the pregnant womb is doubly acted upon, with the result that delivery is effected.

If the thyroid secretion fails in its effect upon the endometrium of a pregnant woman, some believe that toxins are formed in the syncytium which disturb the liver function as well as the renal, and may lead to an abortion, pernicious vomiting, or even eclampsia.

As the internal secretion of the ovary recedes, the effect of the hypophysis and adrenal, as well as the thyroid, is not properly balanced, and, periodic bleeding being absent, we often find augmentation of arterial tension. This is not a pathology of the bloodvessels and not so serious as the usual high-tension states.

Not so many years ago, considering the long period that man has existed, education of the forebrain gradually was instituted, and this for several centuries was the pleasure of the male sex solely. As a result, man became differentiated from woman in strength of mind, breadth of vision, and ability to balance logically opinions on matters brought to his judgment. Woman was still kept either on the farm or in the home. She was not considered man's equal, simply his helpmate and companion in pleasure.

But recently, in the countries where education has advanced, there has been given to her a mind which is observant, a mind whose forebrain is not dwarfed by false speculation, and we have now developed in the female a being who is not as subject to man, who is not so strongly influenced by intuition, and whose thought is clear and unhampered by emotion. The woman of today is not the woman of the past, nor of the recent past. If she be given a hypophyseal body, strong and vigorous, she will have an equally strong, vigorous, and sensible mind. If she be given an adrenal body, persecuted by viscerotoposis, intestinal stasis, and diseased functioning of the endocrines, then she will suffer.

We cannot cure malformations which nature has wrought, but with our knowledge of hygiene, diet, and endocrine stimulation we can do much to relieve them. It has long been known that there exists a correlation between the tissues of the different parts of the body, that no one organ can be affected without another responding and sympathizing. We know there is a strong relation between the physiology and pathology of the female pelvic organs and the kidney, liver, stomach, heart, and brain and the different endocrines, particularly the thyroid, adrenal, and pituitary. Let us not forget that, correctly speaking, gynecology means a study of woman. With the specialists it refers simply to the diseases of woman.

The gynecologist whose mind is in the pelvis becomes narrow. He fails to comprehend many existing conditions and misses the great beauty of the Symphony of Nature. To do full duty by woman, to succeed in relieving her of that distress which

focuses its symptoms and signs below, one must not only know the unfortunate malformations and diseases which are the result of artificial modern life, but must know woman from all viewpoints, her anthropology, her biology, and her wonderfully perfected psyche.

250 MONTGOMERY STREET.

CHRONIC PULMONARY INFLAMMATION IN YOUNG ADULTS.

By FRANK PORTER MILLER, M.D.,

LOS ANGELES, CAL.

THE great majority of the cases which constitute a basis for this article were the victims of influenza. In this discussion I wish to touch upon some common types of inflammation in children, namely tuberculosis, bronchiectasis, and post-influenzal thickening. I wish also to point out the ease with which a diagnosis may be made—though in the main the condition remains unrecognized—and to offer a few suggestions incident to treatment. These children should be spoken of as small adults, as we did not have access to infants, the age period being somewhat variable, ranging from five to sixteen years.

Although a prodigious effort has been made by various writers to cover post-influenzal complications, that portion which is relegated to the pediatrician has received only meager attention; and this is unwarranted. Admitting that the physical findings are not compatible with the subjective sensations, it offers a problem which, because of its obscurity, is peculiarly interesting. It is a common fault that, when examining these children and being unable to elicit signs which, to our mind, are indicative of pathology, we turn to the trusting parent and state that "as growth proceeds in the child there is a tendency for the condition to right itself"; and the patient is dismissed undiagnosed and untreated.

It is highly imperative that these children be placed under judicious management for a prolonged period. The response in these cases is quite as sluggish as in the adult form, but the results are far more gratifying; and I have no hesitancy in stating that, if these children have access to proper treatment, the results at times are nothing short of brilliant. In the event that these cases remain untreated they offer a fertile field for later developments, and it is essential that this period be bridged by a rigorous régime.

Pulmonary tuberculosis usually advances in three stages, namely, (1) period of implantation; that is the time at which the host becomes infected, and this may occur at any time from infancy until the pubertal age is attained. This must be true if we accept Hamburger's conception that practically all children become infected before fifteen years of age. (2) Period of extension. (3) Parenchymal destruction. When tubercle bacilli fall upon virgin soil there is conferred upon the host an immunity which apparently persists through the 'teens, though this is somewhat variable. The clinical evidence to prove the above hypothesis is that frequent sputum examination seldom reveals the organism, even though the refined, so-called

"homogenizing method" is employed. The immunity at this age is great enough to prevent parenchymal destruction, but lacks the power to inhibit extension of the process. After the age of sixteen this immunological effect apparently decreases and the organisms are more numerous in the sputum.

In early childhood the initial infection manifests itself around the hilus and the bronchial bifurcation, involving the epibronchial, peribronchial, tracheo-bronchial, and bronchopulmonary glands; and it seems that these glands check the inroads of the virus, causing the process to remain quiescent for a period, which later becomes reactivated when an acute intercurrent infection supervenes. Then the second stage is reached, the period of extension. As the process extends it limits itself mostly to the bronchi, producing a peribronchial thickening.

The symptoms which are attributed to hilus tuberculosis in children have been described as vague and indefinite, and most writers have described only the toxic group and those which would occur with any lymphatic diathesis, not necessarily tuberculous. The symptoms are quite distinct and, if the history is carefully taken, a diagnosis can practically be made from this alone. The most outstanding symptom of hilus tuberculosis in which there has been some extension is "frequent and protracted colds." Practically all these cases are associated with elevated temperature and invariably a diagnosis of bronchopneumonia will be made, unless one is on the alert for this condition. These attacks always produce some expectoration if the child has been taught to expectorate. In the interval between exacerbations the temperature may return to normal, although a great majority of cases continue to run a slight elevation of temperature. It is our observation that too much significance should not be attributed to temperature in children, meaning by that a temperature ranging from 99° to 100°. The instability of the nervous system, which is manifested mostly through the sympathetic division producing a lessened dissipation of heat, is quite often the causative factor in these children; and it does not necessarily imply that an infective process is the underlying basis. It is necessary to labor the point that instability of the nervous system in young adults must be borne in mind when deducing conclusions relative to the temperature.

As has been shown by Ott,¹ the thermogenic center is located in the tubercinerium, with subordinate centers in the corpus striatum and spinal cord. The tubercinerium is the floor and anterior wall of the third ventricle and belongs, according to Cajal, to the pars optica of the optic thalamus. Edinger believes that the central gray matter of the midbrain contains the central apparatus of the sympathetic. In the event that this is true thermoregulation would occur as a result of stimulation reaching this portion of the brain. In children of this age an unstable nervous system is to be expected, and a hesitancy should be adopted in arriving at a diagnosis when the outstanding symptom is fever.

In this series very few of the cases had lost any appreciable weight. A more frequent complaint was stationary weight. Blood spitting is almost negligible at this age. Distinct pleuritic attacks are seldom seen, but complaints will often be made

of fleeting pains in the chest. Reflex hoarseness is occasionally noted and is significant when present, but is absent in the majority.

In the physical examination one can easily be deluded because of its negativity. On the affected side there is usually a lessened excursion. That portion of the chest anteriorly which evidences hilus infection is above the second rib, and there is usually degeneration of the skin and subcutaneous tissue with an accentuation of the subclavicular space. The accessory muscles in small children do not offer as great an aid as in older ones because of lack of development; but when the child has attained the age when the musculature is developed they are equally valuable.

Inability to diagnose tuberculosis early in these cases is due to our lack of interpretative power, and insufficient attention is directed toward the asymmetrical degenerative areas upon the chest wall and the tenseness of the shoulder girdle musculature. Posteriorly there is usually a marked degeneration and thinning of the muscles immediately over the hilus region, the degeneration being most marked over the side of greatest involvement. If the process is of long standing there is a flattening of the shoulder muscles—particularly the trapezius and levator anguli scapulae. The mechanism producing the above is due to stimulation within the lung, irritating the fibers of the upper six thoracic segments. The afferent sensory impulse courses centralward to the cord, then by interconnecting neurons reaches the third and fourth cervical segments and mediates with the cervical spinal nerves. As has been pointed out by Pottenger,² all degenerative areas above the second rib anteriorly and the spine of the scapula posteriorly are due to a chronic inflammatory lesion of the lungs.

Mediastinal shifting was noted in a number of the cases, frequently without a history of pneumonia, so the natural conclusion one would deduce is that an upper lobe pneumonia had occurred, but was undiagnosed; and the contraction was great enough to produce the shifting. The remaining physical findings were not particularly noteworthy, and we might add that frank pulmonary rales were seldom elicited.

In hilus tuberculosis with slight extension these children appear perfectly normal, response to effort is good, and we should not be misled because the stigmata are lacking.

X-ray examination would usually reveal the hilus shadows of either side markedly increased, and peribronchial streamers extending outward through the lung, frequently to the periphery. The mottling which is present in the early adult form of tuberculosis was equally distinct in these cases.

Bronchiectasis.—Unquestionably the weakening of the bronchial wall is the most important, probably the essential factor in inducing bronchiectasis, since the wall is not able to resist the pressure of air which occurs during a paroxysm of severe coughing. Particularly is this true in those cases which follow whooping cough; and since whooping cough has been quite prevalent in this section of the country during the last few months, it offers a comparatively large number of bronchiectatic cases. Bronchiectasis increases in proportion to the fre-

quency of influenza in any community, and is even more prone to occur if the influenza was associated with pneumonia. It has been known for a long time that if a diligent search is maintained in sputum from these cases influenza bacilli can be recovered in the majority. There is one other type in which pneumonia, influenza, and whooping cough do not play the leading role, and that is the form which follows repeated attacks of bronchitis, often dating back to infancy to the so-called "croupy babies."

We have rather taken advantage of the term bronchiectasis by including in this category all those cases of infected bronchi, even though the x-ray fail to reveal saccular dilatation. If we await x-ray evidence for a diagnosis of this condition in children, the greater percentage will remain undiagnosed. Again allow me to reiterate that the history is of paramount importance, and the aforementioned diseases usually comprise the groundwork.

These cases possess a characteristic cough which, once heard, is not easily forgotten. The "looseness" of the cough is absolutely diagnostic, and I can only describe it by contrasting it to the cough which occurs in an acute bronchitis when it has reached the expectorant stage. This has recently been explained in this manner: If the sacculatation occurs in the primary bronchi, the ingress and egress of air are capable of moving the foreign body back and forth, hence this characteristic rattle upon coughing. Again, the diminution in the excursion of the chest offers a valuable lead, usually a short, high-pitched percussion note upon the side of involvement, and rhonchi are usually present in at least 75 per cent. of the cases. It is not unusual for the rhonchi to be transmitted to the unaffected side. Pulmonary rales are not present. When a limiting membrane is formed in the lung which inhibits extension of a chronic inflammatory mass, rales are never present. In the production of rales it is necessary for the contiguous cells to have undergone destruction, and such is not the case; even though a peripneumonic process surrounds the bronchiectatic area the cells remain intact. The same will also hold true from lung abscess. This explanation was advanced by Pottenger,³ and appears quite plausible. Muscular degenerative areas and shoulder girdle tenseness are absent because sufficient lung substance is not involved.

No attempt has been made to compile statistics relative to locus of incidence; but I feel safe in stating that there were as many cases limited to the upper lobe as there were to the lower.

Postinfluenzal Thickening.—The symptoms presented by this group were analogous to those already mentioned, but following the rule of most air-borne infections, it would produce its pathology in the lower lobe. Even though we attempted to be very meticulous, it was often quite impossible to ascertain the exact etiology without the use of the intradermal tuberculin test. The dosage that we employed was one-tenth c.c. of a 1-5000 solution of Koch's old tuberculin, and with this dosage constitutional symptoms were negligible. The intradermal test has a number of advantages over some of the other tests because of the more exact dosage, the earlier reaction, and the certainty of absorption. It also offers a method of determining the degree

of hypersensitiveness of patients with active tuberculosis and aids one in gauging the rapidity with which the tuberculin may be administered.

Treatment.—These children were given tuberculin and in cases where indicated a mixed respiratory vaccine was also added. A cold sponge bath was given immediately upon arising, the portion of body sponged including the chest and arms. After the temperature had receded, sun baths were instituted, beginning with five minutes a day, and increasing five minutes each day until one hour was reached. It is our plan to have these children rest at least twelve hours each night and two hours during the day, and to allow them to play the rest of the time without any effort at restraint.

In conjunction with the above iodides are usually given. The preparation that we use most frequently is the syrup of hydriodic acid and the compound syrup of the hypophosphites.

Jobling and Petersen⁴ have shown that the anti-ferments contained in tubercle bacilli and in tuberculous caseous material are due to the unsaturated fatty acid radicals of the lipoids. When iodides are taken into the tissues a portion of the iodine combines with the unsaturated carbon atoms of the fatty acids. As soon as this occurs in necrotic tissue, so as to remove the antiferment action, autolysis ensues.

The action of the hypophosphites is rather hazy, although it has been thought for a long period that they produce favorable metabolic changes.

A CONCEPT OF X-RAY PATHOLOGY.

VII. CRANIOPATHY.

By A. J. PACINI, M.D.,

WASHINGTON, D. C.

CHIEF OF LABORATORY AND X-RAY SECTION, HOSPITAL DIVISION,
U. S. PUBLIC HEALTH SERVICE.

SINUSES.—The technology involved for the production of the x-ray plate of the sinuses, including the frontal, ethmoid, sphenoid, and supraorbital, is outlined in Hirsch's "Principles and Practice of Roentgenological Technique," pages 143 to 154. In the frontal sinus study, the method is to demonstrate the fluid level when there collects in the cavity a purulent secretion. No extraordinary success has attended this endeavor. The x-ray pathology of sinusitis is determined by the relative radiopacity in the two sides. In general a normal frontal sinus in postero-anterior view is radiolucent; in lateral view, it is radiopaque. The reason for the difference lies in the fact that in the postero-anterior the outline of the sinus is radiographed through the posterior cranial structures and the skull contents, whereas in the lateral view there is relatively less structure other than sinus to be penetrated by the x-ray.

There does not seem to be any difference in the radiopacity produced by the accumulation of pus or as a result of granulation tissue. In some instances the pus collection will cast a relatively more radiopaque shadow than would be cast by the granulation. It is only safe to infer that the obfuscation leading to radiopacity invades a particular sinus when the companion to that sinus is obviously more radiolucent. It is not certain that variations in the extent of sinus anatomy or in the structure of a cavity indicate any certain finding. The frontal sinuses may be completely absent or hemilaterally absent. They may be small or large and multilobular. In the absence of frontal sinuses the lateral plate is of great assistance in arriving at an inference.

The ethmoid sinuses are generally involved when the frontal sinuses show change. In many instances, if not in all, there is a communicating channel between the ethmoid and frontal sinuses on the same side; so that when the frontal is attacked, by gravitation, the underlying ethmoid may become infected; and, conversely, when the ethmoid is first infected the inflammatory products may extend up into the frontal sinuses. The inference of the presence of diseased ethmoids is made by comparing those on the left against those on the right.

In a relatively large number of cases the ethmoids may encircle the orbit as the layer of air cells inferior to the superciliary ridge. In other instances these air vessels may be present in the same location without apparent connection with the ethmoids. Sinuses in this location are known as supraorbital. They are subject to the same pathological changes as the other accessory sinuses and their x-ray pathology is similarly elicited.

In the study of the sphenoidal sinuses the lateral view or the oral view afford some information. In the case of the sphenoidal sinus the inference of x-ray pathology is more difficult than in the remaining sinuses by reason of the fact that there is no mate for comparison. In the changes that involve equally the entire sinus a diagnostic inference is more difficult to arrive at than when only a portion of the sinus is attacked; for in the latter case the infected sinus part can be compared to the uninfected part. Polypi can sometimes be visualized as rounded areas of whorled radiopacity extending into the sinus cavity from a pedicle attached to the bony surfaces. The patency and course of the nasal ducts can be determined by the x-ray with a probe *in situ*.

Highmore's Antrum.—This may be studied extraorally in antero-posterior and postero-anterior view or intraorally through the use of dental films. The changes affecting the antrum are not unlike those affecting the other accessory sinuses and are inferred from x-ray evidence by comparing one side to the other. The avenue of infection for the antrum is different than for the paranasal sinuses; and therefore the antrum may not be infected contemporaneously with the frontal sinuses. In the maxillary antrum any thickening of the mucus membrane may cause an increase in the radiolucency of the affected side. The greater the inequality and the more complete the obliteration of the sinus of the affected side, the more probable is the diagnosis of empyema.

Mastoid.—Three types of mastoid may be found.

These are the pneumatic, the diploic and the sclerosed. The x-ray plate of the mastoid region must be made for both sides, the x-ray pathology being arrived at by comparing the right with the left. The plates should show seven structures with clear definition:

1. The articulation of the lower jaw and the posterior border of the ascending ramus.
2. The auditory canal, about a quarter of an inch beyond the articulation of the lower jaw.
3. The air cells of the mastoid extending backward in the network from the articulation of the jaw. The air cells often extend much beyond the limit of the mastoid process. They are large in the lower part and become gradually smaller above.
4. Surrounding the auditory canal a dense area superimposed on the mastoid cells and representing the petrous bone should be visualized.
5. The outline of the lateral sinus should be visible as a radiolucent streak that courses through the posterior half of the cells.
6. The foramen magnum should appear as an elliptical orifice crossed by part of the first vertebra.
7. The pinna of the ear should be outlined either reflected from or in its natural position, depending upon the technology used.

Acute mastoiditis shows a general radiopacity of the entire region; an increased radiopacity of the petrous bone, apparent radiopacity of the lateral sinus, obliteration by radiopaque infiltration of some air cells and a haziness due to a radiolucent infiltration of other air cells. These findings must be present on one side but absent on the other. It is possible to conceive of a bilateral mastoiditis so that the relative comparison might be quite futile; but in the vast majority of cases a mastoiditis is unilateral, or if bilateral it is more intense on one side than on the other.

Chronic mastoiditis is more typically characteristic and presents:

1. Obliteration of air cells owing to radiopaque infiltration.
2. Markedly radiopaque petrous bone visualized as a triangular area with the area directed upwards and backwards.
3. The posterior part of the petrous bone presents a distinct and sharp crescentic outline which corresponds to the upper and anterior border of the lateral sinus.
4. The lateral sinus stands out distinctly markedly radioparent in contrast to the dense radiopaque structures that surround it.

INFECTIOUS INVOLVEMENTS OF CRANIAL BONE.—Bone may suffer inflammation due to osteomyelitis, syphilis, tuberculosis, actinomycosis or phosphorus necrosis.

Osteomyelitis is rarely an independent affection localized in the skull. It is more often metastatic. It occurs usually in the frontal parietal or temporal bones. The base is rarely ever affected.

Syphilis of the Skull.—Syphilis of the skull is not an infrequent manifestation. The changes produced affect the region of the face and vault and more rarely the base. When the base is involved the changes chiefly center in the sphenoid bone. Any stage of lues may affect the skull. In the early stages, tophic swellings consisting of granulation tissue accumulate between the bone and peri-

osteum on the outer surface of the frontal, the parietal, or the temporal bone. The underlying bone becomes radiolucent owing to the osteoporosis and the external table becomes perforated with radiolucent and radiopaque holes indicating canals. When the tophi heal calcification is produced with resulting sclerosis of the bone and thickening or exostoses on the surface manifested by dense radiopacity.

In the latter stages gummata may be localized in one or more places. The bone appears gnawed and osteoporotic over large areas. Later in the process bone production is stimulated and there is visualized a sclerosis of the diploë which progresses in places even to a condition of eburnation together with massive thickening of the bone.

Hereditary syphilis may manifest itself on the skull in one of three forms: (1) As an ulcerative process, much resembling acquired lues. (2) As a disturbance in the growth and union of sutures and fissures exemplified by the "saddle nose." (3) Hydrocephalic enlargement.

Tuberculosis of the Skull.—In contradistinction to syphilis, tuberculosis rarely attacks the skull. When present it invades those bones that hold air chambers, the infection seemingly extending from the mucus lining of the sinus through the periosteum into the bone. Tuberculosis may also be found on the bones of the skull usually as an extension of tuberculous infection involving the first vertebra. Two forms generally present. The first is a sequestering, the second is a progressive infiltrating form. *Actinomycosis* rather favors bones of the skull, spreading, it seems, from a decayed tooth into the jaws, into the face, and thence on to the bones of the skull. It produces its typical carious destruction resembling a chronic osteomyelitis, which indeed it is. It is characterized by its slow course and by the pronounced proliferation of bone with resulting intense radiopacity owing to the density of newly formed osseous deposit.

Phosphorus necrosis of the skull also arises from a tooth socket and produces a decay that follows the same channels as that pursued by actinomycosis. In phosphorus necrosis a chronic osteomyelitic change is induced in the bone that cannot be distinguished by the x-ray pathology from pyogenic forms of osteomyelitis.

ATROPHIC AND HYPEROSTOTIC CHANGES.—In this group the local manifestations of systemic diseases, osteomalacia, acromegaly, Paget's disease, and hyperplastic osteitis, are included; and, additionally such conditions as basilar invagination, neurotic atrophy, and basilar hyperostosis.

Senile Atrophy.—Thinning of the skull bone occurring as a wasting of osseous substance is found usually in the parietal region, the outer surface of which region assumes a trough-like depression. The osteoporosis begins in the external table, erosion of which lays bare the spongy diploë or diploëtic area.

The air chambers sometimes diminish in size (maxillary sinus) or they may increase in size (frontal sinus). The general shape of the skull in the aged presents characteristic orientation in cases of senile atrophy. In summary, the x-ray pathology of this condition, to which no great clinical significance is attributable, consists in the thin-

ning and osteoporosis of the parietal skull wall with the trough-like excavation, erosion of bone in the region of the sella turcica, enlargement of the frontal air chambers and sometimes widening of the diploë veins.

Osteomalacia.—In this condition there is an extreme and irregular diminution in the radiopacity of the skull bone (as well as the remaining skeletal bones). It is doubtful if osteomalacia is a separate disease entity, there being much dispute as to its pathogenesis. The x-ray pathology is included in the recognition of the general halisteris. The reabsorption of lime may proceed to an extent where the bone radiopacity approaches the radiolucency of the surrounding soft tissues. It resembles fragilitas ossium and osteogenesis imperfecta, both occurring in young children under one year and readily confusable with rickets.

Neurotic Atrophy.—Under this title are included those changes in the skeleton that occur in diseases of the nervous system and depend upon a disturbance of the trophic function of the latter. It is a rare condition in the skull; and although Schüller includes a discussion of this entity, as do Möbius and Furnrohr and Sudeck, there is little to be gained from the x-ray pathology of the condition.

Basilar Invagination.—The striking x-ray characteristic of this peculiar change is the upward bulging of the floor of the posterior cranial fossa in the region of the foramen magnum. Together with this change, which can best be visualized stereoscopically, there is noted also considerable anomaly in the structure of the wall of the posterior cranial fossa revealed by great thinning. The atlas and axis (epistropheus) are rudimentary, and there is some erosion of the inner surface of the skull.

TUMORS OF THE SKULL.—These have already been discussed under the various tumors in connection with the study of bones. Tumors of the hypophysis will be studied under the caption of sella turcica.

CEPHALOMETRY AND CRANIOMETRY.—It is customary to reserve the term cephalometry for those measures made on the living head, or head without removal of the soft parts, and craniometry for measures of the dry skull. A useful x-ray investigation is that under the title of "Radiographic Base Line," elaborated by Knox and Salmond. A description of the base line is taken from "Radiography and Radio-Therapeutics," by Knox, as follows:

In practice it has been found accurate for application to the various types of skull met with, though in exceptional yet still normal types its accuracy will be lessened.

A base line, which may be called the radiographic base line of the skull, is made use of. It is determined by drawing a line from the nasion, i.e. the mid-point of the suture between the frontal and nasal bones, through the center of the external auditory meatus, and continuing it to the mid-line at the back of the head (Figure 13). The length of this is measured, and on it three points are marked, at the one-third, the one-half, and the two-thirds distance from either end; usually it is most convenient to measure from the front.

Through these points perpendiculars to the base line are drawn, dividing the head into four areas, by three lines which run downwards and forwards and are intersected by the base line. The lines may be marked on the head with a skin pencil, or by thin wire if they are to be reproduced on the plate. This base line was

chosen because the nasion is a fairly constant point and easily determined; the external auditory meatus is also constant, and the whole line corresponds exceedingly well with the base of the skull.

The external occipital protuberance was avoided because it is variable and not always easy to feel, and, moreover, a line between the nasion and the external occipital protuberance does not correspond to the base of the skull as well as the one chosen.

Relations of the Radiographic Base Line of the Skull.—The following points are found on the same horizontal plane as the base line (Figure 13): (1) The lower part of the frontal sinus; (2) sphenoidal sinus; (3) apex of the petrous bone; (4) clivus of the sphenoid; (5) glenoid cavity and condyle of the lower jaw; (6) external auditory meatus; (7) jugular foramen; and (8) base of the mastoid process.

The point of intersection at the one-third distance from the nasion is at the zygomatic malar suture and corresponds in the interior with the front part of the sphenoidal sinus. The point at the one-half distance is at the glenoid fossa and condyle of the lower part of the dorsum sellæ or just a little behind it, the apex of the petrous bone. The point at the two-thirds distance is on the mastoid process, toward its posterior margin, and corresponds with the curved portion of the lateral sinus in the interior.

If in the interior of the skull a mesial base line is drawn between the ends of the corresponding base line on the exterior it will be found that the intersecting lines at the one-third and at the one-half distance correspond in both cases, but that the intersecting line at the two-thirds distance on the exterior base line corresponds to a point at the three-quarter distance on the mesial line in the interior.

Relations of the Perpendicular Lines and the Areas Defined by Them.—The perpendicular at the one-third distance corresponds with three sutures of the skull, the coronal, the squamo-sphenoidal, the speno-maxillary, in order from the above downward (Figure 13). It bisects the frontal lobe of the brain, and roughly divides the face from the hairy scalp.

The perpendicular at the one-half distance approximately corresponds at its upper end with the fissure of Rolando, and below the base line with the posterior margin of the ascending ramus of the lower jaw.

The perpendicular at the two-thirds distance bisects the parietal lobe of the brain.

These three lines divide the head into four regions, which may be called A, B, C, D, from before backwards.

Region A contains the anterior fossa of the skull with the anterior half of the frontal lobe, the orbits and the facial bones with the exception of the ascending rami of the lower jaws and the palate bones.

Region B contains the body of the sphenoid and the greater part of the sphenoidal sinus, the sella turcica and the pituitary body, the palate bones and the ascending rami of the lower jaw, the posterior half of the frontal and the anterior part of the temporo-sphenoidal lobe of the brain.

Region C contains the mastoid process, petrous temporal bone, occipital condyles, anterior half of the parietal and posterior part of temporal lobes of the cerebrum, the pons, medulla, and anterior part of the cerebellum.

Region D contains the horizontal portion of the lateral sinus, the occipital lobe and posterior half of the parietal lobe of the cerebrum, and the posterior part of the cerebellum.

As an illustration of the use of the system: To radiograph the sphenoidal sinus laterally. The system shows that the base line runs through the sinus, and that it is situated between the intersecting lines at the one-third and one-half distance. The tube is therefore arranged so that its central rays pass through the base line and between the intersecting lines.

The technique necessary in this system of measurement need be only briefly indicated.

The patient may be radiographed with the head in either the vertical or horizontal position—in other words, the sagittal suture should be parallel to the plate, a point of importance in order that a region localized on one side of the skull may exactly correspond with the similar region on the other side; for accurate work of this kind a head rest is essential.

The side to be radiographed is placed next to the plate, the opposite side being made use of for localization.

When in proper position the tube is central over the base line of one side, and the two lines will be found to coincide exactly; or if the tube is centered over the perpendicular drawn at the one-half distance, then both perpendiculars at that point on the two sides of the head will be found to coincide.

In the localization of bullets or shrapnel in the brain this system may be used in conjunction with the cross-thread method of Sir James Mackenzie Davidson. It can also be used in conjunction with the ordinary stereoscopic method, the resulting negative or prints being viewed from the point chosen before the tube was shifted to either side.

In order to facilitate the ready selection of points from which to radiograph the skull the use of a special cassette with mechanical adjustments is advisable.

It is strange that there has not been an effort to devise measures of the dry skull or measures of the living skull directly from x-ray evidence. In this connection the topic of craniometry will be discussed.

Craniometry.—It seems that precise measurements of the skull were first initiated by artists who endeavored to attain greater accuracy in their representation of the human form. Bernard de Palissy and Durer were early pioneers in these researches. In the Middle Ages there arose a dispute as to whether Galenic anatomy was based upon the study of the human body or upon those of apes; and this seems to be the determining cause in the improvement of craniometric technique. Thus, Tyson, in 1680, explains that the measurements he made of the skull of a chimpanzee at dissection were devised with the view to exhibiting the difference between this and the human skull.

Daubenton, in 1764, published a valuable contribution to craniometry; but six years later, Pieter Camper, distinguished both as an artist and anatomist, published in lecture form an account of craniometry that forms the foundation for all subsequent work in this field.

Camper, in the first place, was interested in arriving at the distinguishing characteristics between animal and human faces. This wide comparison was the first motive for craniometric investigation; and it is remarkable that among the first measurements observed, angular determinations occur. Indeed, the name of Camper is perpetuated in anthropological literature with the "facial angle"; and it is impossible to improve on the simple terms with which the artist-anatomist described the general significance of the measure. Said Camper, "The two extremities of the facial line are from 70 to 80 degrees from the Negro to the Grecian antique; make it under 70, and you describe an orang or ape: lessen it still more, and you have the head of a dog. Increase the minimum and you form a fowl, a snipe for example, the facial line of which is nearly parallel with the horizon." To this very important observation, the approach to the horizontal in the facial angle, x-rayists' attention will shortly be invited.

Broca in France and Huxley in England elaborated the science of craniometry with a genius that has yet to be surpassed.

The second aim of craniometry rests in comparing skulls of higher and lower races of mankind. To this field of research must be added the names of

Retzius of Stockholm, whose claim to distinction rests on the merit of his system of comparing various dimensions of the skull, and a classification based upon these dimensions. It should be mentioned here for convenience that the pristine aim of craniometry was to obtain from the skull reliable data having reference to the conformation or size of the brain once contained in it. This fundamental aim was for a long time afterward overlooked, much to the detriment of craniometric science.

As the measurements become more accurate, and comparisons obvious, craniometry reached into a third horizon of usefulness, that of comparing skulls of the same race, but of different sub-races. Thus, the fair and dark European were contrasted. It is in this specialized branch of craniometry that Retzius reached his highest fame. Retzius studied not any one particular angle or measure, but an expression of relative measurements, using as an index the two cranial measurements of breadth and length. A skull, Retzius ascertained, could be so proportioned that the relation between breadth and length was as three is to four, or 75 per cent ratio. This is the cephalic index. The long, or anteroposterior diameter is taken as 100; the short is correspondingly proportioned. If the short falls below 80 the skull is classed as long (dolichocephalic); if it extends 80, the skull is broad (brachycephalic). Retzius applied his system to the inhabitants of Sweden and strikingly observed a contrast between the Lapps and their Scandinavian neighbors, adding a craniometric difference to the usually observed characteristics of hair-color, stature and complexion. Broca followed these studies with a survey of Basques and Gaunches skulls.

The fourth division of craniometry deals with the comparison of prehistoric and present mankind. The methods exactly simulate those advanced by Retzius, using special modifications in those instances where only fragmentary pieces of prehistoric skull are obtainable. In this field the names of His and Rutimeyer (Switzerland), Ecker (South Germany), Broca (France), and Thurman and Davis (England), must be particularly cited. Schaalbe, Kramberger, Sollas, and Klaatsch are the more recent contributors.

As the complexity of craniometric studies increased, the number of measurements to arrive at a "diagnosis" in any given skull reached a colossal total. The more recent tendencies, therefore, became threefold; first, an attempt to coordinate the systems of measurement and strive for uniformity among all observers. In this, two attempts deserve mention, the German Anthropologists at Frankfurt, in 1882, and the Anthropometric Committee of the British Association in 1906. Secondly, a statistical collection of anthropometric data collected and compiled by Pearson. Third, the extension of craniometric studies to domestic and feral animals.*

As valuable as are craniometric studies for the purposes which called them into being, they are practically worthless to the clinician; and the sur-

geon and physician, when interested in skull measures taken *in vivo*, has had to resort to other measures, similar to dry skull measures but varying in the result, accuracy, and, to some extent, in significance. In contradistinction to craniometry (measurement of the dry skull) measures of the living head are classified under the title cephalometry. The uses for cerebral topography in surgical intervention need little rehearsal. The cephalometric methods devised for their identification, as for instance the outlining of the Rolandic fissure course, are known to all surgeons and require no further elaboration. But a phase of skull study has remained manifestly unexplored; or if investigated, the inquiries have been superficial and the inferences drawn from data manifestly seriously wanting in accuracy and discrimination. That phase is the relation of skull conformation to the various psychiatric disorders.

Lombroso, like Bovio, Ferri, and Colojanni before him, was influenced by Auguste Comte in the tendency to refer all mental phenomena to biological causes. There need be no defense for some of Lombroso's work. He studied at Padua, Vienna and Paris. He was then appointed professor of psychiatry at Pavia; then he became director of the lunatic asylum at Pesaro; later professor of forensic medicine and psychiatry at Turin, and finally professor of criminology at Turin. He made brilliant observations upon the relation between cranial conformation and mental state; but his work was confined entirely to cephalometric measures, no attention having then been given to the possibilities of x-ray exploitation. Much of Lombroso's work recalls the fantastic thoughts propounded many years previously by Gall in connection with the system of empirical psychology called by Forster phrenology, which, under a more popular garb, has just recently been reintroduced in the form of character reading and analysis, based upon facial and cranial form.

It is anthropometrically established that the various nationalities present some differences in their craniometric conformation; and that in the same nationality presenting splits in the original descendancy, each branch of racial progression shows variances characteristic for the sub-nationality. Thus, the native southern Italian, who is of psychomotor excitability, presents cranial conformations distinguishable from those of the native Hollander, who manifests normally psychomotor retardation. Now, if an Italian develops psychomotor retardation, he would likely be considered a psychic in the depressive stage; and, contrariwise, if the Hollander developed psychomotor excitability, he would be suspiciously regarded as a psychic in the manic stage. Their outward cranial (cephalometric) conformation might be nearly identical; or, as is more often the case, the manic Dutchman would show a configuration that more nearly approaches the native normal Italian; and the depressed Italian would show an outline simulating the normal Dutchman.

Several examples of this sort came under actual observation. Cases of manic depressive psychosis in Italians and Dutchmen, the Italians in the depressive stage and the Dutchmen in the manic stage. They were compared in cephalometric dimensions with the manic-depressives in both stages

*Sergi headed an Italian movement in revolt against using metrical methods in craniometry. Sergi's substitutes for the measures are not acceptable by the vast majority of those interested in craniometric study; and Sergi's adherents have not been able to sway followers from the orthodox metrical advocates.

of other nationalities. In external appearance, there could be no general conclusion arrived at in the matter of characteristic external conformation, though a tendency to likeness in outline was observed among the manics and depressives regardless of gross national or racial differences. The cases studied were in soldiers referred to mental hospitals for treatment following the late war; and the mental condition was obviously acute, though in hereditary potentiality, 98 per cent of the cases showed "nervous taint" somewhere in the progenitor file.

The cases were x-rayed in sagittal view for skull study. In this, the outer and inner tables were traced. At first, apparent parallelism between the outer and inner tables was found missing; but more scrutinizing observation revealed that the general contour of the inner table was greatly similar in cases showing the same phase of phenomenon; that is, all psychomotor excitable, though racially dis-

rived directly from the x-ray plate without the use of the patient (excepting to procure the x-ray exposure). It should be a method as truly craniometric as the study of the heart silhouette is cardiac. To this end, devised especially in connection with psychiatric needs, the following craniometric system was elaborated and applied to cases of mental patients studied in various institutions.

(To be continued.)

Medicolegal Notes.

Municipal Health Regulations Relating to Mineral Content of Water.—An ordinance of the city of Miami prohibited any person or corporation from selling or supplying to the inhabitants of the city water for human consumption which shall have been taken from wells or other sources of supply "in or without" the city limits, unless the vendor shall hold a valid permit from the city board of health. The manager of a corporation which supplied water to the inhabitants of the city, which water was taken from wells in or near the city, was arrested and charged with the offense under the ordinance of "supplying to patrons" of the corporation water for human consumption "without first securing a permit." The Florida Supreme Court, reversing a conviction, holds that municipalities acting under authority from the State may enact ordinances which are necessary for the public health, although the requirements of such ordinances impose conditions upon persons or corporations not required in contracts which they may have with the city for the particular service affected by the ordinances; but ordinances prohibiting the sale for human consumption of water containing certain elements or compounds as unwholesome or unfit for use may not establish a certain standard of mineral content and declare that water which contains a greater quantity of such minerals is unwholesome if such standard so fixed by the ordinance is not accurate.—Hyman v. Dillon (Fla.) 84 So. 666.

Cause of Hodgkin's Disease Cannot be Conjectured.—In holding that the evidence in a Workmen's Compensation proceeding disclosed no facts that would justify an inference that "Hodgkin's disease," from which the employee died, resulted from ulcerations in the mucous membrane of his nose, or that these ulcerations were caused by inhaling the fumes of hydrochloric acid used by him in his work as a tinner, the Minnesota Supreme Court said: "That acid fumes had been inhaled in soldering can hardly be considered a reason for attributing them (the ulcerations) to such fumes, for there is no evidence that they had their inception at or about the time of such inhalation, and no evidence that injury has ever resulted from inhaling such fumes under such circumstances, although all tanners frequently inhale them. It is undisputed that medical science has not yet discovered how Hodgkin's disease is produced or what causes it, and no attempt was made to show that it follows traumatic injuries or that such injuries have any part in producing it."—State v. District Court, (Minn.) 177 N. W. 644.

Preliminary Education Not Prerequisite to Examination of Graduates in Osteopathy in Wisconsin.—Under Wisconsin Laws of 1915, Chapter 438, as amended by Laws 1915, Chapter 595 (Statute 1919, Section 1435a), the Wisconsin Supreme Court holds that a graduate of a reputable college of osteopathy is entitled to mandamus to compel the State Board of Medical Examiners to examine him in the various branches of surgery in accordance with the usual course of the board, though he had not completed the preliminary education required by the statutes for examination in medicine and surgery. The preliminary education required of one applying for a license to practise osteopathy and surgery is an "education equivalent to graduation from an accredited high school of this State." The additional college course applies only to those desiring to practise medicine and surgery; consequently, in order to constitute colleges of osteopathy reputable, under the terms of this law, it is not necessary that they require of their students the college course.—State v. Wisconsin State Board of Medical Examiners (Wis.), 177 N. W. 910.

FIG. 13.—Diagrammatic representation of the Knox Salmund base line drawn from the nasion through the external auditory canal, then divided at right angles at the middle and again at the one-third and two-third points.

tinguishable from outward cranial contour, manifested a strong resemblance and even identity in inner table conformation; and, similarly, those of psychomotor retardation, while different outwardly, were closely identical inwardly.

From the first series of cases thus studied (124), it became apparent, in the effort to make comparable x-ray studies, that a truly radiographic craniometry did not exist. The so-called radiographic base line of Knox and Salmund, above discussed, was after all a cephalometric measure reproduced on the x-ray plate; and any benefit to be derived from it had to be in terms of translation from radiography to cephalometry.

Knox and Salmund's base line, and similarly Reid's and the Frankfort base line, are not veritable x-ray entities. They are cephalometric. The necessity for an x-ray craniometry is obvious. It should aim to secure accurate intracranial measures de-

MEDICAL RECORD.

SYPHILITIC NEPHRITIS.

So many unquestioned cases of secondary syphilitic nephritis have been recorded that this renal manifestation of syphilitic infection can not be denied and it should be included among the numerous early visceral localizations of lues. It frequently occurs in the second month of the infection. Out of a total of twenty-three cases mentioned by Mauriac the renal accidents appeared during the sixth month of the infection. Of seventeen cases Dieulafoy mentions two arising in the eighth month of syphilis, two in the sixth, two in the fourth, five in the third and five in the second month, and he is of the opinion that the renal process occurs more frequently during the second and third months following the chancre. It often appears at the same time as the roseola. Descout reports a case of abundant albuminuria appearing on the fifty-third day of syphilis.

When the nephritis occurs early and is intense there is usually a massive albuminuria without any other symptom, but edema and hydrothorax have been known to occur. However, there is an early type in which the albuminuria is slight (20 to 30 centigrams per liter). The urinary toxicity, urea and extractive matter are in normal proportion and the microscope will reveal a few casts. The albumin disappears under treatment. It is nevertheless true that these early intense syphilitic nephritides with massive albuminuria are by far the most frequent.

Usually the onset is insidious, there being only some slight malaise, a general tired feeling, or a slight rise in temperature. Sometimes it is more manifest, edema appearing first. Both Jaccoud and Dieulafoy have insisted on these cases in which edema becomes the main symptom. It may become generalized at once or remain localized to the eyelids, lower limbs or external genital organs. Lumbar and joint pain or headache may appear at the same time. Fever is often absent, but when it exists it may be accompanied by digestive disturbances with nausea or vomiting. The urine, at first voided in large amount, tends to become scanty, fifty c.c. or less being passed in twenty-four hours. It is cloudy, high colored and contains albumin varying from eight to fifty or more grams per liter. The urea is decreased, while the specific grav-

ity averages from 1014 to 1020; the reaction is usually acid. Cytological examination reveals red blood-corpuscles, epithelial cells and numerous and varied types of casts. Renal permeability is not usually disturbed, but in a few cases a delay in the elimination of methylene blue has been noted. There is never any cardiac hypertrophy nor high blood-pressure.

In some cases death occurs in a few weeks, with progressive general edema, dyspnea and fluid in the serous cavities; other patients recover in a relatively short time. Syphilitic nephritis is especially serious from the rather frequent complications to which it gives rise, such as hyperacute uremic intoxication or progressive uremic accidents with edema of the glottis and lungs, asphyxia and asystolia. According to Fournier, early syphilitic nephritis is fatal in one case out of three and when it retrogresses it is only for a short time. Usually the albuminuria persists and ends in amyloid degeneration of the kidneys after a lapse of several years. Rosenstein reports 32 cases out of a total of 120 in which it was due to syphilis, while out of a total of 265 cases of amyloid change in the kidney, Wagner attributes the lesion to syphilis in 36. The process may remain latent and even be susceptible to cure. Therefore the prognosis of syphilitic nephritis must be very guarded.

When a nephritis coincides with the development of secondary luetic phenomena, the syphilitic nature of the morbid process must be regarded as possible, but other factors such as alcoholism, hepatic or gastrointestinal processes may also be active. A massive albuminuria, the daily amount varying from day to day, is one of the principal characters of specific nephritis, coupled with the presence of undoubted syphilitic infection. Mercury probably plays no part in its production, but the initiative influence of the arsenical preparations cannot be denied and many able clinicians regard them with suspicion in this respect.

DOES THE MENSTRUATING WOMAN DIFFUSE A POISON?

ACCORDING to Schick, the well-known serologist, a menstruating woman may be a veritable upas tree (*Wiener klinische Wochenschrift*, May 20, 1920, xxxiii, 19). His attention was first attracted to the subject on the occasion of receiving ten fresh, long-stemmed roses, which he had requested a female servant to place in water. On the very next morning the roses had largely withered, the petals having dropped on the table. Greatly surprised, he had summoned the servant to illuminate the mystery. She said that she had known that the roses would wither for when she was unwell this phenomenon was always in evidence. Greatly astounded, Schick began to experiment. The woman, along with a non-menstruating control, was sent to the author's gardener who cut off for each an anemone, a white crysanthemum, and a yellow helianthus. The women simply held the flowers in their hands and went to the clinic. Upon their arrival the flowers in the hand

of the menstruating woman had begun to wither and were hanging their heads. The time elapsed was but ten minutes. The blighting process was complete at the end of twenty-four hours, the petals having fallen off at eighteen hours. The flowers handled by the control subject were as fresh as ever at the end of forty-eight hours. The menstruation in this experiment was in its first day only. On the following day the tests were repeated, and flowers held in the hand of the menstruating woman showed some alteration in three minutes after she had taken them. The change consisted of a progressive drying, followed in a few hours by discoloration. The anemones were especially sensitive, and the chrysanthemums showed the greatest resistance. On the third day of menstruation the pernicious effects were but slight, and on the fourth day they had vanished, and during the entire intermenstrual period the woman showed not a trace of this mysterious power.

Schick next learned that there is a popular belief in certain strata that menstruating women have the power of withering freshly cut flowers, although many refuse to believe in it and look upon it as a mere superstition. In wineries menstruating women have been forbidden to enter, and this proscription even extends to orchards, for these women are not allowed to climb into fruit trees when in bloom and even later, lest the fruit crop should spoil. Study of this problem through the ages brings out astounding facts and beliefs. The menstruating one in an orchard can cause the insects to drop from the trees; and even in classical times there were tales of the use of partially exposed women for expelling the cantharis beetle from the trees.

The author, after extended research, was able to show that the menotoxin circulates in the blood but not in the serum; in all probability it is in the blood corpuscles or adherents to them. It must be volatile and escape by the skin or lungs. Schick thinks we are on the threshold of a great discovery, this potent volatile poison being a menace not only to the preservation of certain organic substances, but even to growing flowers. It also seems toxic to insects. In regard to unicellular organisms it can both inhibit and accelerate the proliferation of yeast. The menotoxin is regarded by Schick as something which the female organism must get rid of, and this supports the prevalent view that menstruation is a depurative phenomenon.

PRINCIPLES OF HORMONE THERAPY.

DESPITE the large literature of this subject, an account of the principles underlying the exhibition of internal secretions, rather than their mere indications, should be timely, and such a one by Professor Ascher of Berne has just appeared in the *Schweizerische medizinische Wochenschrift* for November 18, 1920, i, 47. Therapeutics as a branch of applied science devoid of empiricism is the least developed of any of the so-called medical sciences. As Bleuler says it gives free scope to "autistic thinking." The introduction of hormones into therapy does something to make the latter study more scien-

tific, and may mark a turning point of the greatest significance. The secretin of Bayliss and Starling is the first of the actual hormones to serve as a pivot for building up the hormone principle. Secreted in a certain region it is absorbed into the blood from which it is able to activate the functions of one or more special organs. The number of true hormones from this viewpoint is not large. Next to secretin chronologically comes adrenalin which can be synthetically prepared. Thyroxin, the hormone of the thyroid gland, has recently been shown to be a triple iodized indol derivative of adrenalin. The active principle of the hypophysis appears to be a series of biogenic amines. Only secretin of this "big four" has resisted all attempts to solve its intimate chemical nature. Thus far we are not in position to speak with authority on the nature of the hormones of other ductless glands. In reality we cannot even prove the existence of hormones in the pancreas, parathyroids, gonads, etc., because we must first isolate a principle which measures up to the known hormones in being albumin free, in being ferment free, etc. The active principles present may belong under some different class of substances. But for convenience we may speak, for example, of the testicular hormone in connection with the work of Steinach, which is of the most revolutionary character.

Hormones, including those so termed by courtesy, are either general or specific. Secretin is of the latter type and the author in the same class places cholin, which, formed in the intestinal wall, acts upon the ganglia of the mesenteric plexus and thereby presides over the activity of the smooth muscle of the intestine. In addition and considered purely as a drug, cholin has quite a varied physiological action, but plays no added physiological role in nature. Adrenalin is a general hormone which, by activation of the sympathetic nerve fibers, is able to influence nearly every organ in the body. Further, according to circumstances, it can both excite and inhibit action. In severe asthma it relaxes muscle spasm, although commonly supposed to produce contraction of smooth muscle. The double action is not paradoxical because the sympathetic fibers themselves are both excitatory and inhibitory. Even more sweeping in its activities is the thyroid hormone, and the mere enumeration of its purely physiological activities is bewildering to the student. Intermediate between secretin and cholin on the one hand and adrenalin and thyroxin on the other are the hormones of the hypophysis, thymus, spleen, and pancreas.

When we remove a portion of a goiter and rid the subject of the syndrome of hyperthyroidism we are practising negative hormone therapy. This is the surgical, straightforward type, practised by Kocher in his strumectomies for many years. Cushing has done the same work on the hypophysis of the acromegalic, while extirpation of the spleen for hemolytic icterus also belongs here. Still another instance is removal of the thymus, in addition to the thyroid, in Graves' disease. Positive hormone therapy in its most essential form is seen in surgical grafting of the thyroid, gonads, and adrenals.

This kind of work is difficult and attended with numerous failures and as a general resource must give place to feeding.

But the oral administration is limited largely to the thyroid and hypophysis, other gland preparations being more or less unsatisfactory when so given, and even the hypophysis is not in the class with the thyroid. The intravenous method is generally applicable and is the method of choice with adrenalin, while the latter may also be given intramuscularly. Pituitrin is given hypodermically with complete satisfaction.

Since all hormones are toxic in large amounts if not in small, the dosage is a delicate matter. A little excess of adrenalin can unfavorably influence the respiratory center and also cause extrasystole and even heart flutter. There is a factor termed by Hering the "disposition" which must be reckoned with, for variations in the latter require modification of the dose. This disposition is seen only in the tissues upon which the hormones act. Only in this manner can we explain why a given drug, as atropine, will in the same condition produce opposite effects, stimulating in one subject and inhibitory in another, the dose being the same. It is not worth while to pass the subject along by speaking of idiosyncrasies. There is some concrete explanation; perhaps in the case referred to, the presence or absence of cholin in the intestine.

ANNUAL REPORT OF THE SURGEON GENERAL OF THE UNITED STATES PUBLIC HEALTH SERVICE.

To those who think of the United States Public Health Service in terms of wartime and post-bellum activities, it may come in the nature of a surprise to be reminded by the Surgeon General that the report for 1920 is the forty-ninth annual report of the service, covering the one hundred and twenty-second year of its existence. The report includes the activities of the service along the lines of scientific research; domestic (interstate) quarantine; foreign and insular (maritime) quarantine and immigration; sanitary reports and statistics; marine hospitals and relief; venereal diseases; inspections; and public health education.

When one realizes, from looking over the report, that the manifold activities of the service include items varying from the disposition of "picture brides" seeking admission to the country before the completion of uncinariasis treatment in Japan, medical work among detained I. W. W. and other unwelcome guests, to the reconstruction and rehabilitation care of the sick and wounded ex-servicemen, and the conduct of the new public health education service, it is not to be wondered at that among the needs chronicled is the urgent necessity for provision by the Congress of Legislation which will provide adequate and suitable personnel. Perhaps a careful perusal of this report, would deter certain over-zealous denizens of Capitol Hill from spending funds on another of the already long list of doubtfully useful "investigations." The service,

it would seem, deserves to be helped and not hindered in its efforts to carry its old burdens plus all the new ones left it as a heritage of war.

A CASE OF WILSON'S DISEASE.

CASES of this comparatively recently discovered affection are not so well known that an outline of a new one should not possess considerable interest for the average reader. Söderbergh in the *Deutsche Zeitschrift für Nervenheilkunde* (abstract in the *Schweizerische medizinische Wochenschrift* for November 25, 1920, i, 48) gives an account of a boy of 14 who first presented salivation and then eruptions. Nine months after supervention of the former, he complained of headache and occasional vomiting, followed by dysarthria, tremor of the hands, and rigidity of the muscles of the face and four limbs. This state of the muscles of the lower limbs affected the gait. Dysphagia is the next symptom mentioned. The tremor with paresis involved the tongue, dysarthria became pronounced, and speech became slow and monotonous. The movements became slow with synkineses, there were a fine tremor with agitation in the upper extremities, pigmentation in the skin and margins of the corneae, defective teeth, palpatory enlargement of the liver and spleen, transitory ascites, defective development of the genitals, etc.—in fact a typical Wilson's disease. The two last named symptoms had not before been placed on record. The author in discussing extrapyramidal movement-disturbances insists that these display better static than dynamic functioning; that the muscular hypertonia is really dystonia and that the increased knee jerks are only apparent—that is, are due to rigidity and absent when this subsides. The general muscular rigidity is partly direct and partly associated. Pathological skin and soft-part reflexes are responsible in part for the dystonia.

CHRONOLOGICAL RELATIONS OF EPIDEMIC ENCEPHALITIS AND INFLUENZA.

BAUER and Mayor have incidentally worked out these relationships in an article on encephalitis in the *Revue médicale de la Suisse romande* for October, 1920, xl, 10. There was a pandemic of influenza in Europe during the period 1709-1712, and it was in the latter year that the first episode of encephalitis was recorded. In 1846-1848 there was also a pandemic of influenza which ravaged Europe, and in 1846 Dubini described what seems to have been the myoclonic form of encephalitis. During the pandemic which raged in Europe from 1889 to the early nineties, the disease *nona* appeared in Italy and Austria. In all of these cases influenza seems to have preceded the brain disorder or at least did not follow it; but during the last pandemic the "sleeping sickness," as it was then called, seems to have preceded the grippe, for it began in the winter of 1916-17, while the influenza did not gain headway until the Spring of 1918. At least this is true of the cases seen in Vienna by Economo and Pribram. But we must remember that a large fraction of the incidence of the encephalitis, and especially its global diffusion, distinctly followed the influenza, appearing in the winter of 1918-19.

Moreover it is certain that the onset of the influenza pandemic goes back beyond the Spring of 1918, although how far we cannot state. Encephalitis appeared in Europe outside of Austria in the winter of 1917-18, when its appearance was noted in both France and England. The Swiss authors are not disturbed by the apparent reversal of priority in the last appearance of the two maladies, for it is not at all inconceivable that influenza was active for a long time before the great outbreak in May 1918.

COMPLICATED NEOPLASTIC AFFECTIONS.

THE French Association for the Study of Cancer has recently been devoting its energies to investigations into tumors of the mixed class and rare neoplasms in general, as appears from a report of a recent session in *La Presse Médicale* for December 8, 1920, xxviii, 90. Hartmann and Renaud report a case of mixed or associated cancer and tuberculosis of the breast. This was the clinical and microscopic diagnosis, but study of sections failed to locate Koch's bacillus. The safe explanation was the autonomy of both conditions, but it is of course possible that the cancer process somehow caused the formation of pseudotubercles in the connective tissue. Masson and Wolf presented collectively two cases of plasmocytoma. In one a tumor of a rib propagated itself to the vertebral column, while in the other there were growths in the cranium, pharynx, and vertebrae and also in the liver. In both subjects the growths all consisted of plasma cells only. The second case at least would ordinarily be termed a sarcoma which could be styled plasmosarcoma. Lecène presented a specimen of cancer of the corpus uteri, which in some sections was a cylindrical and in others a pavement epithelial cancer. The association points to heterotopia of squamous cells in the mucosa of the cavum uteri. Milian, who sought to cure a lymphangioma of the abdominal wall with undosed x-rays, appeared to have transformed it into an ulcerated and vegetating lesion which gave rise to metastases in the regional lymphnodes. These metastases were of the same nature as the parent growth. Thus far no melanotic tissue had been seen, but in a local recurrence there were islets of melanoma.

CARATÉS OR PINTA.

THIS familiar affection of intertropical America is described from the latest data by Neveu-Lemaire in *La Presse Médicale* for October 16, 1920, xxviii, 75. The names denote one and the same malady, a mycosis which produces a variegated discoloration of the skin akin to that of tinea versicolor. It was named by Alibert in 1820 the endemic spots of the Cordilleras. The spots are known in certain countries as caratés with the addition of the particular hue—violet, red, blue, yellow, white, or black. The color varies with the natural color of the skin of the native, which may be white, red, or brown or black. The term *pinto* or *mal de los pintos* refers to the painted or mottled appearance of the subject. The word *caraté* suggests a mask, and the affection begins as a rule on the face, where it is very conspicuous. The disease progresses until the body is nearly covered and gives off an offensive odor. Cure

with parasitic remedies is difficult but the body remains indelibly stained. In Colombia 4 per cent. of the natives are attacked. The northern limits are in southern Mexico and the affection is present as far south as Venezuela and Ecuador, while exceptionally it follows along the Andes as far as Chile. Naturally it flourishes in the whole of Central America and has been seen in some of the Antilles as Hayti and Martinique. Some striking peculiarities are the absence of any one particular fungus (for several forms of tinea as well as the *Aspergillus* may be concerned in the individual case), and the noncontagious character of the malady which, however, may be artificially inoculated. Certain insects are suspected of transmitting the disease. The latter is readily avoided by cleanliness, including the wearing of shoes.

News of the Week.

Bill Providing for Five War Hospitals Passes.—The House, on February 7, passed a bill to expend \$12,000,000 for the construction of five hospitals to care for wounded soldiers in different parts of the country, and an additional \$500,000 to convert into hospitals the barracks at Fort Walla Walla, Wash., and Fort McKenzie, Wyo. The bill carries a provision authorizing the Secretary of the Treasury to enter into an agreement with the Commission for Military Hospitals for the State of New York to lease the hospital building on Creedmoor rifle range on Long Island. This hospital, the construction of which has been provided for by the New York State Legislature, will cost the State \$3,000,000. The Federal Government will pay an annual rental of \$300,000 and will use the hospital for the treatment of gassed soldiers. The bill does not designate the location of the hospitals, but provides that one shall be built in the Central Atlantic Coast States, one in the Great Lakes region, one in the Rocky Mountain States, and one in Southern California. The Senate also has ratified this bill. It, however, makes a total appropriation of \$18,000,000 available through amendments attached to the Sundry Civil Bill. One of these amendments would appropriate \$12,500,000 for five new hospitals, the location to be decided by the Surgeon General of the Public Health Service and the President, and the other would provide \$6,100,000 for the care of disabled veterans through improvements or new construction of Public Health Service Hospitals.

Madame Curie to Visit America.—Madame Marie Curie plans to come to this country in May and make quite an extended visit, according to an announcement made by Dr. Francis Carter Wood of the Crocker Memorial Cancer Research Laboratory, chairman of the committee which is to receive Madame Curie. During her stay here Madame Curie will receive a gram of radium with which to experiment, the gift of a number of American women now engaged in raising the Madame Curie Radium Fund. Only women will be permitted to subscribe to this fund. Women's committees are being organized in New York, Boston, and Pittsburgh who will have charge of contributions to the fund.

Relief Unit Reaches Poland.—The medical unit of fourteen American Jewish doctors, headed by

Dr. Harry Plotz, which was sent out by the Joint Distribution Committee for American Jewish Relief, Arrived in Warsaw on February 6.

Red Cross Supplies Are Given to China.—The Shanghai Branch of the American Red Cross has completed the distribution of more than \$500,000 worth of medical and hospital supplies to mission dispensaries and hospitals in all parts of China. The materials given away were mostly those left behind in Siberia when the American Red Cross was withdrawn. Among the supplies were five complete sets of surgical instruments, many of which might not be obtainable in Chinese markets.

Harvey Society Lecture.—Dr. A. N. Richards, Professor of Pharmacology, University of Pennsylvania, will deliver the seventh Harvey Society Lecture at the New York Academy of Medicine, Saturday evening, Feb. 26, 1921. His subject will be "Kidney Function."

The Association for the Prevention and Relief of Heart Disease, elected at its third annual meeting, held on February 7, the following members to the board of governors: For a term of five years, Drs. T. Stuart Hart, John W. Brannan, Robert N. Halsey, Charles Hendee Smith, and E. G. Stillman; for the term of one year, Mrs. Alfred E. Hess.

Western Electrotherapeutic Association.—The third annual meeting of this association will be held at the Little Theater, Kansas City, Mo., under the presidency of Dr. B. B. Grover of Colorado Springs, on April 21 and 22, 1921. Further information and programs can be obtained from the secretary, Dr. Charles Wood Fassett, 115 East 31st Street, Kansas City, Mo.

Health Officials Take Action Against Typhus.—The discovery that immigrant ships have brought to the Port of New York 38 cases of typhus fever within a week has aroused Federal, State, and city health officials to action. Following the discovery of twenty cases of typhus fever among the steerage passengers of the Italian steamship *San Giusto* from Trieste and Naples, on February 11, Dr. Leiland E. Cofer, Health Officer of the Port, ordered the vessel to remain at anchor off Quarantine until sufficient time has elapsed to determine whether other passengers have been infected with the disease. Several other steamships are being held at Quarantine for the same reason. Steamship companies booking immigrants at Trieste, Naples and other ports are to be warned by health authorities here that it will be wise to exercise the utmost vigilance. American consuls in Italy have been instructed to refuse clean bills of health to vessels whose medical inspection has not been satisfactory. The New York City Health Department has arranged with Major General Robert Lee Bullard, Commander of the Department of the East, for the use of the United States Army vermin-exterminating plant at Hoboken for the disinfection of immigrants. A fumigation order has been issued requiring vessels from certain ports to be fumigated on arrival every voyage, from other ports every four months and from still others every six months. The typhus cases from both the *Presidente Wilson* and the *San Giusto* are being cared for on Hoffman Island. The Health Department has issued a bulletin to the physicians of the city describing the

symptoms of typhus fever, which they are urged to keep in mind so that cases may not be overlooked. The announcement is now made that vessels arriving at the Port of New York will be held in quarantine until the expiration of twelve days from the date of their departure from the home port. If we are to go back to a medieval quarantine why not make it the full forty days so as to be etymologically correct? It would be no more absurd.

Dr. Abraham L. Wolbarst has removed his office to 792 Lexington Avenue, New York City.

Dr. William H. Stewart has resigned as director of the Department of Roentgenology of the Brooklyn Diagnostic Clinic.

Dr. Franklin H. Martin, secretary-general of the American College of Surgeons, recently sailed for South America for the purpose of familiarizing the surgeons of the South American countries with the work of the American College of Surgeons and inviting them to pursue their studies in this country instead of in Europe.

Charitable Bequests.—The will of Mrs. Eloise L. Breese Norrie makes bequests of \$1,000 each to the New York Skin and Cancer Hospital, Woman's Hospital, St. Mary's Free Hospital, Society for the Relief of the Destitute Blind, and the Society for the Prevention of Cruelty to Animals.

The Medical Section of the American Life Convention will hold its eleventh annual meeting at the Elms Hotel, Excelsior Springs, Mo., March 16-18, 1921. The chairman of the Medical Section is Dr. F. L. Truitt and the secretary Dr. F. L. B. Jenney of Chicago.

Legislation Aids Fight Against Disease.—The Senate at Albany has passed a measure introduced by Senator John J. Boylan which aims to remove the \$80,000 limit on expenditures the New York City Health Department may incur in excess of its appropriation to ward off contagious and infectious diseases. The bill was supported by Health Commissioner Royal S. Copeland as a result of his apprehension that the plagues of Europe may gain a foothold in this country. The passage of the measure by the Assembly is practically assured.

New York May Abolish the Drug Board.—Two bills, one introduced into the Senate by Senator George Fearon and the other into the Assembly by Miss Marguerite Smith, propose to abolish the State Department of Narcotic Drug Control. The bills provide for a bureau in the State Department of Health to carry on the work and also amend the present State narcotic drug law to make it conform more closely to the Harrison Act.

Schick Test Used in Buffalo and Canandaigua.—The February *Bulletin* of the State Department of Health reports that in all private institutions having a large number of child residents the Department of Health of the City of Buffalo is using the Schick test to determine which children are susceptible to diphtheria and is immunizing those found to be nonimmune. It is expected that in the near future the same preventive measures will be used in the public schools of that city. In Canandaigua the test is being applied to all school children presenting cards signed by their parents giving the necessary permission.

Jamestown, N. Y., to Install Municipal Milk Plant.—The citizens of Jamestown have author-

ized a bond issue of \$150,000 for the construction and equipment of a milk pasteurizing and distributing plant to be operated by the city. It is planned to have each can of milk brought to the plant tested separately, and to pasteurize all milk except grade "A" milk from tuberculin tested herds. The milk will be handled under the best sanitary conditions from the time it reaches the plant until it is delivered to the consumer. It is believed that by the elimination of the duplication of effort in delivery a great saving in the cost of handling will be effected whereby the consumer will be benefited.

Clinics Consolidate.—Plans are being worked out for the consolidation of the Clinic for Functional Reeducation, the Demilt Dispensary, the Institute for the Crippled and Disabled, and the Park Hospital. The organization resulting from the affiliation of these institutions will be known as the Reconstruction Hospital.

New Heart and Tension Clinic.—Through its president, Dr. Louis Faugeres Bishop, the Good Samaritan Dispensary announces that it has opened a heart and tension clinic which is to be conducted along unique lines. Everyone accepted for treatment is to have a complete technical examination, including an orthodiagram, an electrocardiogram, a polygram, a uranalysis, a blood count and Wassermann test, also a month's observation of blood pressure, hygienic and therapeutic tests. A small fee will be charged for the service. It is believed that in this institution, which has been in existence for ninety years and treats sixty to seventy thousand people a year, there is an opportunity to carry on a good work in the prevention and relief of heart troubles, and that by giving a complete examination to all who desire it many conditions will be discovered in their early stages that are now overlooked.

The Eye Sight Conservation Council, of which L. W. Wallace of New York City is president, is initiating a nation-wide campaign to acquaint the public with the importance of eye care and to urge universal eye examinations of school children, industrial workers, and clerks in offices and stores. The organization invites the cooperation of all existing agencies concerned in any degree with the movement for better vision, particularly the ophthalmologists of the country.

Rural Locations for Physicians.—The New York State Department of Health announces that the following towns in New York State should be added to the list of communities where medical service is inadequate or lacking: Brushton, Franklin County (for further information write Mr. George W. Harris, Brushton, N. Y.); Burke, Franklin County (write Mr. George Smith, Burke, N. Y.), and Richville, St. Lawrence County (write Mr. Frank Beaman, Richville, N. Y.).

Obituary Notes.—Dr. LUIS FERNANDEZ CRIADO, a graduate of the College of Physicians and Surgeons in 1879, died at his home in New York City on February 7. He was a member of the New York Academy of Medicine.

Dr. JOHN L. BORSCH, who was born in Bavaria, and for thirty years practised ophthalmology in Philadelphia, died at his home in Atlantic City on February 9, at the age of seventy-five years. He was the inventor of rimless eyeglasses, and pat-

ented the kryptok bifocal lenses and the full back reform artificial eye. He was also the first oculist in America to use oval astigmatic lenses.

Dr. WILLIAM M. WELCH, chief consulting physician on contagious diseases at the Municipal Hospital in Philadelphia, died on February 8, at the age of eighty-three years. Dr. Welch was a graduate of the University of Pennsylvania, in 1857, and was later clinical professor of medicine in the Graduate School of Medicine of the university. He was formerly president of the Medical Society of the State of Pennsylvania.

Dr. FRANK PROAL HATFIELD, a graduate of the Long Island College Hospital, in 1899, died suddenly following an operation for appendicitis, in St. Joseph's Hospital, Far Rockaway, N. Y., on February 5, at the age of forty-nine years. He was visiting surgeon at St. Joseph's and the Rockaway Beach hospitals, and physician at St. Malachi's Home.

Dr. GABRIEL HARRISON PARKHURST, formerly of Brooklyn, died at his home in Allendale, N. J., on January 29, in his eighty-fifth year. He was graduated from the Castleton Medical College in 1860.

Dr. BURR BURTON MOSHER of Brooklyn, N. Y., died from the result of injuries received in a motor car accident nearly a year ago, on January 31, at the age of fifty-four years. He was graduated from the Long Island College Hospital in 1890. He was surgeon-in-chief to the House of Giles the Cripple, consulting physician to the Wayside Home, assistant surgeon at the Brooklyn Eye and Ear Hospital and the Orthopedic Dispensary.

Correspondence.

"A MESSAGE OF HOPE."

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the MEDICAL RECORD for February 5, the President of the American Society for the Control of Cancer suggests the above title as one that could be well used in regard to the work of the Society, which has been in existence almost eight years.

The Good Book says "Hope deferred maketh the heart sick," and it is difficult to see wherein that Society, or others of similar name, have offered any hope either to those already afflicted or to the millions of human beings who would be glad to know how they may escape cancer. For the name of the Society indicates a desire to control the dread disease, and surely "control" should include prevention, which is always more important than an attempt to cure. As far as can be learned from this address or from all the publications of the Society, the only purpose, however, seems to be to incite every one to a surgical operation, both when a well defined tumor has been formed, and also upon the discovery of a mole, or wart, or nevus, which the surgeons choose to call and remove as precancerous; whereas millions of such exist on human beings without resulting in cancer, unless the person has carcinoma, or the dyscrasia of cancer. For we must remember that the local lump or lesion to which the name cancer is given is only the product or result of a long-continued systemic error.

A careful study of the United States yearly Mortality Tables would convince any one of the futility of such a proceeding. Under wise and careful medical treatment the mortality of tuberculosis has *fallen* nearly 30 per cent. since 1900, while that of cancer, under surgical management, has actually *risen* nearly the same 30 per cent. in that period.

It is a lamentable fact, also disclosed in the same tables of statistics, that in the year 1915, which directly followed the crusade of certain over-zealous surgeons throughout the country, propagating such ideas, that there was a *rise* in cancer mortality which was actually more than *double* the average rise during the preceding five years! There could hardly be any other cause that could produce such a result in a single year. It is strange indeed that such blindness should affect the medical profession, and through them the laity, when it is acknowledged now by the surgeons that 90 per cent. of those once attacked by cancer die therefrom. A recent study of the death statistics of the Board of Health of New York City* has revealed the really alarming fact that during the period from July 1, to December 31, 1920, the deaths from cancer had *actually exceeded* those from tuberculosis by 22—2691 to 2669, and this in spite of radium aiding surgery. Is it not time to call a halt, and see if we are on the right track in regard to our understanding and treatment of cancer?

The trouble all along has been that studies on cancer have been made too much on animals, and too little along the lines of careful clinical observations of human beings, in all their relations of life—forgetting Pope's admonition that "the proper study of mankind is man."

Led by honest, industrious, intelligent, and capable pathological laboratory workers, clinicians have regarded cancer as a local disease, whereas it has been abundantly shown and declared by any number of good clinical observers, surgeons as well as physicians, that is a constitutional disease, quite as much as are gout and many other affections. In the latter a derangement of tissue cells takes on an inflammatory form or character, and in the former (cancer) a neoplastic one, both of them from an erroneous pabulum, a faulty blood and lymph stream. Exactly why this is so we may perhaps never know; indeed we now know not much more about the actual pathogenesis of gout than we do about that of cancer, but experience has taught us how to reach the former by correct dietetic, hygienic, and medicinal measures, and many of us have learned the same about cancer, with gratifying results. It is quite as rational to excise a gouty toe, a syphilitic gumma, or a tuberculous lesion as it is to expect really to cure the carcinosis by the simple removal of the offending tumor, or *product* of the disease. And yet the writer referred to distinctly says in two places that cancer is not a blood disease.

It would be interesting to hear from the members of the Society for the Control of Cancer as to what they claim has been accomplished by any of the Societies toward the "control of cancer." While some active surgeons may claim a higher percentage of so-called cures, for a few years, than others, some of the best men have declared that they do

nothing to cure the disease permanently, but only attempt to remove the offending lesion—and we all know in what an enormous proportion of internal cancer there is recurrence, or a fresh development of lesions. (Cutaneous epithelioma is excluded from our study, for obvious reasons.) The immediate result of the surgical procedure may be, or perhaps generally is successful, but those of us who have had much to do with the disease for many years, know full well in what a very large proportion of cases there is distressing recurrence, either soon after the earliest possible operation, or later, even many years thereafter—simply because no measures are used to overcome the real, basic cause of the disease.

The immediate aims of the Society, as quoted by the writer from Greenough,* who has charge of enlightening the Eastern States, are to attack the cancer problem along four lines: "(1) The education of the public as to the early symptoms of the disease. (2) The instruction of the medical profession as to the actual facts of this serious situation, to bring about earlier diagnosis. (3) The promotion of investigations on the part of surgeons, in regard to more effective means of operative treatment. (4) The promotion of investigations in the laboratory in regard to the causes of cancer, and of methods of treatment other than by operation."

The first and fourth of these contain germs of truth which must be accepted by all. Unquestionably the sooner the early symptoms of cancer are detected the more chance there is for the patient, possibly surgically but most certainly medically. For when the system is thoroughly saturated with what is sometimes called the cancer virus (which does not exist) that is, when metastases have formed in lymph glands and other tissues, surgeons and even x-ray and radium experts acknowledge that there is little or no chance of curing the disease permanently. But with minute and proper dietetic, hygienic, and medical treatment not only can early lesions be made to disappear, but metastases yield, and the cancerous habit is overcome, and the patient remains well indefinitely, provided the proper course is pursued indefinitely.

Hope is certainly engendered when the patient knows this, and the fear of the knife and its unfortunate results are taken away, and when this becomes widely known many will seek proper medical aid with the first possible suspicion that cancer may develop. Thus, the public should most certainly be educated to look out for this, and be so instructed that they will be able to recognize its very earliest manifestations.

But this is not all in regard to the "control of cancer" for which this and other similar Societies should exist. At present its efforts relate in a small measure to some possible benefit or control in individual cases, but do not look at all towards its racial control—for statistics from many countries show unquestionably that cancer mortality is increasing steadily, even as was tuberculosis before 1900, until intelligent medical activity had effected its control and reduced its death rate nearly 30 per cent.

*Greenough: *New York Medical Journal*, October 16, 1920.

*Bulkeley: *MEDICAL RECORD*, January 29, 1921.

What shall be said of the 80,000 new cases of cancer developing each year in this country, to make up for the 80,000 deaths from this terrible malady? How does the American Society for the Control of Cancer propose to check the steady advance of this cruel enemy? Not a word of this occurs, as far as I know, in any of their publications, and I have read all that I could obtain. What also in regard to the about 300,000 sufferers from cancer now existing in the United States? For with the estimated length of life, at from 3 to 5 years, of these patients, from the beginning to the fatal issue, there are probably fully that number now affected, which number must be increasing yearly with the continued increase in mortality.

The fourth mentioned object of the Society does contain a germ of hope, when it speaks of seeking "the cause of cancer and methods of treatment other than by operation." Surely after all that has been written in regard to the failure of laboratory investigations to add anything to the practical knowledge of the treatment of carcinosis, and all that has been written by careful clinical observers and investigators in regard to the real, basic, internal causes of cancer, and the reported favorable results from following just the right line of treatment, there should be no question as to the advisability of urging the medical profession and laity to follow the lead of this star of hope, and not hark back to the cry for more surgery, with its sad record of the past. An eminent pathologist has recently remarked "the day of cancer surgery is past. There is nothing in it." And Ewing,* from a pathological standpoint distinctly states, regarding cancer of the breast, "There can be no doubt that operation shortens life and aggravates the terminal suffering in the great majority of recurrent cases," which I have long observed from a clinical standpoint.

Moreover, in regard to cancer in general, Dr. J. Aebli† has twice reported in regard to cancer mortality in Switzerland in a manner which should attract attention. He presents the statistics from 1900 to 1915, and compares the life duration of cancer patients operated on with those not operated on, estimating the expectancy from the very first symptom. From these it would appear that operative treatment either reduces the life expectancy, or else that it has such a slight influence that it may be regarded as negligible. And all this is based not on cases submitted to any definite line of dietary or medicinal treatment, but to those simply left alone under ordinary medical care. As so many know, if these unoperated cases had been cared for according to the present well established lines of treatment the contrast would have been very startling.

L. DUNCAN BULKLEY, M.D.

Bone of Vesalius Discovered by Radiography.—Laquerrière states that the Vesalian bone is a supernumerary bone which lies at the base of the fifth metatarsal. In his opinion it is not always a supernumerary bone, for in some cases it appears to be an ununited abnormal epiphysis. In either case one should know about this bone, for to one ignoring its existence it would pass as a fracture.—*Le Presse Médicale*.

INCREASING RESTRICTIONS ON MEDICAL PRACTICE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The difficulty experienced by Dr. Beverley Robinson in getting a little laudanum for his own use is as nothing compared to the difficulty he will have in getting a little brandy if the Volstead act is engrafted upon the statutes of New York.

Under this law, which the Governor has requested the Legislature to pass, a physician cannot prescribe an alcoholic beverage for himself even though he is given a "license" to prescribe it for others. Unless in an emergency he can find a physician or is attended by one he might in some remote region pass away for want of a few ounces of "eau de vie," even if it were at hand in unlimited quantity for others who know how to get it without a "prescription."

I am informed on good authority that one dealer at least who has made a fortune by the illicit sale of liquor and who was anxious to retire with his gains before he was caught, is prevented from doing so by those from whom he obtains his supplies. All attempts on his part to close out his business are frustrated by those from whom he obtained his wares by their constant renewal of his stock despite his efforts to restrain them. Who these purveyors are is not difficult to imagine. The current news of the day will afford a clue to their identity.

MEDICUS.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, January 21, 1921.

Discussion on the Interim Report of the Consultative Committee of the Ministry of Health.—At a special general meeting of the West London Medico-Chirurgical Society held in London on Jan. 14, last, the Interim Report of the Consultative Committee of the Ministry of Health was discussed. The discussion was opened by Dr. F. J. Lloyd, who pointed out the importance to the whole profession of the subjects dealt with in the Report. The Report was largely the development of the Cavendish lecture in 1918 on the "Future of the Medical Profession" delivered by Lord Dawson of Penn. Dr. Lloyd made special reference to the benefits that "team work" would give to the public and the help that the general practitioner would receive from it. He strongly recommended the profession to concentrate their efforts to procure by this means all the help that modern research could give. He pointed out that in this direction the medical profession in Great Britain was not so up to date as such countries as Switzerland, America, and France. So far as the hospitals were concerned he was strongly in favor of the retention of the voluntary system as opposed to State control. He suggested that the retention of the voluntary system would constitute the best possible "war memorial" to those that had fallen. It would require the united and concentrated effort of the medical profession and public to ensure the salvation of the voluntary system. Lieutenant-Colonel E. M. Wilson was opposed to State Control of the hospitals, and considered that a great deal might be done to relieve the financial position of the hospitals by instituting

some system of voluntary contributions from the patients. This system was already at work in some of the hospitals and had proved very satisfactory. He thought that contributions according to the financial position of the patient was better than a "flat-rate" system and he hoped if some such scheme was adopted that the hospitals might thus avoid the necessity of State aid which must necessarily involve some amount of control in the management. Dr. I. Orr said the first question to be considered was whether the medical treatment provided for the people of this country was sufficient. The examination of recruits during the war showed the great amount of preventable disability which existed, and it was largely on account of this finding that the Ministry of Health was established. The Consultative Committee had the duty of advising the ministry as to the best methods for preventing the continuance of this serious state of affairs. The Dawson Report was the result. He thought that the scheme proposed would cost an enormous sum of money, and it was the duty of the profession to consider whether it should be adopted in whole or part. The President, Dr. E. J. McCann said there appeared to be a general desire to see the voluntary system of hospital administration continued in Great Britain. He held that State control should be strenuously opposed as it would not make for the advancement of science. In his opinion "team work" was essential if the patients were to obtain the maximum benefit from scientific medicine. He thought that the scheme mapped out by the Ministry of Health would be very costly and that the tax-payers would refuse to contribute the money. He pleaded for the establishment of maternity hospitals and centers without delay, and pointed out the grave necessity for these in the country.

Attention was drawn to the point mentioned in a previous letter that while the scheme sketched in the Interim Report was perhaps utopian and even somewhat grandiose, it was for the public benefit that it had been drafted. Some parts of the Report should be carried into effect at once, notably the establishment of maternity centers.

The Electron Theory in Percussion.—Probably most medical men in America know something about Abrams' electron theory in percussion. The pith of this theory is that he has shown that percussion is influenced by visceral tonicity and that the latter varies with reference to the posture of the patient to the points of the compass. He has also shown that a disregard of the electronic mechanism of the organism may conduce to errors in percussion when the organism is short-circuited. Sir James Barr of Liverpool, is a firm believer in this theory, and in the *Medical Press and Circular* of Jan. 26, in his customary emphatic and breezy style, explains the theory and dilates upon it. He has himself put the principles enunciated by Abrams to practical test with very considerable success, especially in the diagnosis of cancer, and states that in his opinion the methods are effective at the very inception of diseases and thus at a time when they are amenable to treatment. He holds that Abrams' greatest achievement, because most widely applicable, has been in the early diagnosis and treatment of tuberculosis.

The editor of the *Medical Press and Circular* entirely agrees with Barr as to the diagnostic value of percussion and rightly remarks that it depends essentially upon the physician's power of interpretation and this is a variable quantity. However, he does not permit himself to criticise the electron theory of percussion.

The Early Recognition of Tabes.—An argument is going on in the correspondence pages of the *Lancet* between certain authorities on syphilis as to whether syphilis is really absolutely curable. Dr. E. Farghar Buzzard had this to say on the subject: "We are all asked 'How long must I go on with treatment before I am cured?' For many years my answer had been 'For the rest of your life.' I am never consulted about a primary chancre, if so, my advice would be the same." In short, he does not believe that syphilis is ever perhaps absolutely cured or rather that in any one case a practitioner is justified in making a definite statement that the disease is cured. Dr. John Donald, on the other hand, makes the dogmatic statement that if a patient first comes under treatment while the blood is still negative (it is here the Wassermann test is of prime value), if he then receives the usual course of 606 and mercury, the disease will be knocked out. Dr. Buzzard in answer to Dr. Donald says: "If you take a hundred cases of syphilis and treat them all according to the standard methods of the day you are justified in believing that a certain proportion will have been cured, but you cannot honestly tell any single one of these patients that his disease has been eradicated." Dr. E. T. Burke of Manchester, strongly supports and corroborates Dr. Buzzard and further points out that the Wassermann test is far from being infallible. He too says that the most that can be done is to tell the patient that he is non-infectious. To get a patient to this stage is comparatively easy, but having reached this stage, and having obtained a negative blood Wassermann, it is certainly not justifiable to stop all treatment and give the assurance that aortitis, aneurysm, or central nervous system syphilis are now impossible. Dr. Burke makes the unqualified statement that as a test of cure the Wassermann reaction is treacherous, perhaps worthless. The only real test is an undoubted reinfection, but many of the reported cases are merely recurrences. The majority of medical men who have had considerable experience in dealing with syphilis are more likely to agree with Drs. Buzzard and Burke than with Dr. Donald, and to be on the safe side it is better for the individual who has contracted syphilis to be treated at intervals throughout life. If this course were more frequently pursued there would be fewer cases of locomotor ataxia.

 2. Foreign Bodies as a Cause of Appendicitis. S. A. Mahoney.
 3. Some Instances of Diverticulitis of the Sigmoid Opening into the Bladder. A. L. Chute.
 4. Observations on Cancer of the Rectum. Ernest A. Wells.
2. Foreign Bodies as a Cause of Appendicitis.—S. A. Mahoney, from a digest of the literature of the sub-

ject, finds that pins compose 55.5 per cent. of all cases of true foreign bodies found in the appendix. Out of a list of seventy-four cases of true foreign bodies pins occurred in forty. The natural supposition that pins would be found mostly in the appendices of women was not substantiated in this investigation, the majority having occurred in men. Fruit seeds were next in frequency, having been found in seven out of the seventy-four cases.

1. **Endocrinasthenia.**—William W. P. Garretson points out that the interrelation between the nervous system and the endocrines is a very potent factor in the production of reciprocal expressions of dysfunction, hence in the treatment of the so-called functional disturbances of the nervous system, the balancing of endocrine dysfunction is quite essential before one can obtain a curative reaction from psychotherapeutic procedures. It is in relation to this field of work that his interest in endocrine function and therapy was primarily stimulated. Large groups of patients referred to the neurologist, whose symptomatology is not consistent with the usual etiological objective evidence, in whom no organic disease is discernible, and who complain mainly of subjective symptoms, one has been prone to consider victims of psychic traumata and repressed complexes, and one finds in the vast majority that such is the case. The elimination of the psychic irritant, however, is only a small part of the problem. The continued assault of the psychic irritant will not express its symptomatology until it has been sufficient to undermine the balance of the endocrines, and after its removal the return to normal health will not occur until the endocrine readjustment is effected, and if this important phase of therapy is neglected, recurrent and continued symptoms will obtain. Endocrinasthenia not only occurs as a result of exhaustion reactions, expressed through the nervous system, but is always present as a sequel to every disease process, and more particularly the acute infections. All toxic states exhaust the glands of internal secretion, and the degree of infection and toxemia depends entirely upon the quantitative and qualitative balance of the hormones. That to which one has loosely referred as body resistance is dependent upon this balance. Endocrinasthenia invariably begins with exhaustion symptoms expressed through one gland primarily, and subsequently by compensatory efforts other glands of the chain inject into the symptomatology disturbances produced by their dysfunction, and thus the entire chain may become so fatigued as to produce a generalized endocrinasthenia. It frequently occurs that in this compensatory effort on the part of other glands to aid the exhausted member of the group, one of the compensating glands may become hyperactive and in its overaction produce a chemically perverted hormone. This is always the case in hyperthyroidism. In analysing such a case one should determine by a detailed history which member of the group was originally assaulted, and thus sequentially the subsequent glandular dysfunctions created by the primary imbalance may be determined. In supplying the patient with the gland substance to meet the deficiencies of the primarily exhausted gland, the balance may thus be scientifically and accurately adjusted. In profound asthenic states of long standing it is often essential to use more than one gland substance. Four illustrative cases are cited.

8. **The Effect of the Thymus and Mammary on Menstruation.**—Adolph Jacoby deduces from his study of the subject that the inhibition of the ovary alone is

not sufficient to influence menstruation, as is shown by the failure of the extract of thymus alone to cause any change; that the extracts are quite effective in the control of menstruation in the majority of cases; that the combined extracts act better than either alone. This is to be expected, as it is rare to have a disturbance of the internal secretions involving only one gland; and just as infrequent to have the disturbance corrected by the administration of a single suitable extract.

10. **The Management of Toxic Goiter with Radiation.**—J. Thompson Stevens states that metabolism tests show that at least ninety per cent. of the toxic goiters can be cured by proper roentgen therapy. Radiation properly carried out is at present the method of choice in many of the medical centers throughout the world. It does not disfigure the patient for life, it is decidedly less dangerous, and the results are at least as good, if not better, than those obtained by any other method. The danger just mentioned refers to high tension shock. Many of the patients who are referred for radiation are those that are too ill to withstand operations and those that have had operative failures. The results obtained in these cases only serve to prove that radiation is the best method in properly selected cases. An outline of the possibilities of both surgery and radiation should be presented to each patient suffering with toxic goiter. They will generally select radiation.

2. **Ulcer of the Jejunum Following Gastroenterostomy.**—J. Shelton Horsley begins the discussion of this subject with the statement that ulcer of the jejunum following gastroenterostomy is caused by gastroenterostomy, and holds that even the most ardent advocate of this operation must admit the causal relation. But the manner in which the operation causes the ulcer has been the subject of various interpretations. The probable explanation is that the changed physiology in the jejunum caused by the gastroenterostomy weakens the resistance of its tissues, and that traumas or nonabsorbable sutures that are easily taken care of elsewhere cannot be borne here. The writer holds that there is a distinct field for gastroenterostomy, and gives the indications for this operation and for pyloroplasty: 1. When there is cicatricial stenosis of the pylorus and duodenum so marked that the duodenum cannot be returned to normal, but no bleeding, gastroenterostomy gives excellent results. 2. When there is a subacute perforation of the duodenum with such extensive leucocytic infiltration that its walls will not hold sutures, eventually stenosis is almost certain to occur. Here the tissues will not hold sutures, and pyloroplasty should not be done. 3. In obstruction of the pylorus from inoperable malignant growths, gastroenterostomy is, of course, the proper operation. In most of the other cases, whether the ulcer is located in the body of the stomach or elsewhere, or when pyloric stenosis is confined to a narrow band of tissue, pyloroplasty is indicated. Occasionally the location of the ulcer demands pylorotomy. When the ulcer is in the duodenum and is an inch or more from the pylorus, excision of the ulcer transversely and suturing of the wound in this direction, as practised by Judd, gives excellent results. In such a location the ulcer may be treated without reference to the stomach or pylorus. Horsley has performed twenty-four pyloroplasties by his technique since

the first one in April, 1918. During this time he has performed four gastroenterostomies, one operation of Judd for duodenal ulcer $1\frac{1}{2}$ inches from the pylorus, and two pylorotomies. All of these operations were for ulcer except two of the gastroenterostomies, which were for cancer. He believes that this represents about the correct proportion of pyloroplasties to gastroenterostomies. Of the twenty-four pyloroplasties, three deaths occurred in the first twelve cases. Postmortem revealed the stomach and pylorus in excellent condition. Probably none of these deaths would occur at present. There were no deaths in the last half of the series. For the first few months after a pyloroplasty, the results are similar to those after gastroenterostomy. It is only as the length of time after the operation increases that the advantages of the pyloroplasty begin to appear.

4. Interpretation of Wassermann Reaction of Blood Serum in Mental Diseases.—Jackson and Pike hold that from the standpoint of syphilis as the exciting cause of mental diseases, individual cases fall most naturally into two groups: (1) Cases which, while showing a strongly positive reaction of the blood serum, do not present clinical, neurological, or spinal fluid serological evidences of neurosyphilis; (2) cases which, irrespective of the Wassermann reaction of the blood serum, show clinical, neurological, and spinal fluid serological signs of syphilis of the central nervous system. In Group 1 he places three types of cases: (a) psychoses in which syphilitic infection antedates the development of mental disease; (b) psychoses in which the mental disease antedates the syphilitic infection, and (c) epilepsy, mental deficiency, and psychopathic constitutional inferiority, with syphilitic infection either hereditary or acquired. Cases of representatives of the two groups are reported, and the following conclusions are drawn: (1) A positive Wassermann reaction of the blood serum alone indicates nothing further than that the individual has come in some manner in contact with syphilis, either hereditary or acquired. It does not mean that the mental disorder from which he suffers is due to syphilis. (2) A diagnosis of neurosyphilis should be based on definite serological signs and spinal fluid reactions, irrespective of the readings of the blood serum. (3) Psychoses in which there is a positive Wassermann reaction of the blood serum, but showing no other serological, neurological, or clinical evidences of syphilis do not demand antisyphilitic treatment for the reason that such treatment will not modify the mental condition; furthermore, neurosyphilis is seldom, if ever, superimposed on a well developed psychosis. (4) General systemic syphilis as shown by a history of infection, clinical signs, and positive Wassermann reaction of the blood serum should be treated as such, but not with the view of favorably influencing the psychosis. (5) Antisyphilitic treatment avails nothing in well advanced cases of general paresis or tabes dorsalis. (6) Cerebral, cerebrospinal, and spinal syphilis are amenable to treatment and antisyphilitic therapy should be pushed to the limit. (7) Successful treatment of neurosyphilis resolves itself into the early recognition and therapeutics of the infection, and lies largely in the hands of the general practitioner and syphilographer; all syphilistics should be kept under routine observation for a period of at least ten years in order that vigorous treatment may be instituted at the first signs of involvement of the central nervous system.

3. Amputations: The Effect of War Knowledge on Teaching, Practice, and After-Care.—Edred M. Corner states that experiments with light metal limbs conducted at St. Thomas's Hospital have been most successful, showing that about 90 per cent. of thigh amputations can advantageously be fitted with light metal limbs, with which men are able to work with less fatigue and more satisfaction. It has been found that men fitted with light metal artificial limbs could be more easily and perfectly instructed in the use of their stumps. They learn more easily. In some cases helpful treatment has been given by hypnosis. After-treatment is necessary in most cases—in such a form as return to work without undue delay. Pains and other troubles may recur and then they seem to be more definite than they were formerly. Patients should not be kept in hospitals or homes, but should be sent back to work and healthy surroundings.

5. A Consideration of the Postoperative Mortality of Appendicitis, Especially in Children.—Herbert M. Brown emphasizes the great importance of operation at the earliest possible moment after the commencement of the attack, preferably during the first 24 hours, while the infection is confined within the appendix. But when the patient, a child, is seen for the first time by the surgeon during the third, fourth, fifth, or sixth day, when the infection has spread beyond the appendix and a localized abscess is formed, the alternatives are immediate operation or delay until the second week (when there is considerable immunity to blood infection). He thinks the safer, though certainly not easier, course is to wait, although if anything untoward results the surgeon will probably be blamed for his Fabian tactics. Appendix abscesses very rarely burst into the peritoneal cavity if the patient is kept at rest in bed, on scanty and easily absorbable diet, and the bowels are not disturbed by aperients. During the second week the abscess may be opened and drained with the minimum of danger. But if it is decided to operate at once during the dangerous period it is absolutely essential that nothing but the introduction of a drainage tube into the abscess cavity should be attempted, with no swabbing, no handling, no interference of any kind, and, above all, no removal of the appendix. The latter may be safely done many weeks later when all infection has subsided. The great danger of blood infection occurs especially in children; adults appear to have a far greater power of resistance, but to them, too, the same rule should apply. In cases where there is general peritoneal infection, when the appendix is perforated or gangrenous and free in the abdominal cavity, it should always be removed with as little disturbance as possible, and free drainage to the bottom of the pouch of Douglas with a large drainage-tube, provided, of course, with the Fowler position. It is not justifiable in such case to delay operation, at whatever stage of the disease the patient is seen.

7. A Note on Psychotherapy in General Practice.—W. Thomson Brown has used psychotherapy based on neuro-induction (as opposed to hypnosis or neuro-conduction) since December, 1919, in general practice, as far as the requirements of a busy middle and working-class practice have permitted. He has found it curative in many conditions and also useful in promoting anesthesia for minor operations, dental extractions, and obstetric cases. Three illustrative cases are cited.

 5. On the Action of Certain Special Preparations on Malarial Parasites and Their Employment in the Treatment of Malaria. Major J. Pratt-Johnson, Major Kenneth Gilchrist, and Captain Hay-Michel.
1. An Address on the Part of the Practitioner in the Treatment of the Pre-Operative Stage of Enlarged Prostate.—J. W. Thomson Walker calls attention to the fact that the risks to which a patient suffering from

enlarged prostate, whether he be submitted to operation or treated without operation, is exposed are not confined entirely to the urinary organs. There are gastrointestinal, pulmonary, circulatory, nervous system, and urinary risks. In discussing with the patient the question of operation as opposed to catheter life, the following points are suggested as worthy of consideration: (1) Enlargement of the prostate is a progressive disease, the rate of increase of which cannot be foretold. (2) As the prostate enlarges, the patient grows older, and is less able to withstand the effect of uremia or sepsis, or the effects of a severe operation. (3) When the symptoms become acute, much damage has already been done to the kidneys; and although improvement may follow operation, much of the damage is permanent. (4) Some adenomatous prostates become malignant. (5) The mortality of catheter life is higher than that of prostatectomy. (6) A very large proportion of the cases of enlarged prostate treated by catheter are forced eventually to undergo operation. (7) The prognosis in such cases is much graver than if the operation had been performed without a period of catheter life. (8) A large proportion of the deaths after prostatectomy are due to the sepsis caused by pre-operative catheterization or to the back pressure and renal inefficiency due to delay in submitting to operation.

5. On the Action of Certain Special Preparations on Malarial Parasites and Their Employment in the Treatment of Malaria.—Pratt-Johnson, Gilchrist, and Hay-Michel detail the results of investigations carried out at No. 4 General Hospital, S.A.M.C., Roberts Heights, during 1917-19 on malarial patients invalided from the German East African campaign. The majority of the cases were of a severe type, associated with marked anemia and debility, numerous relapses occurring in hospital while under quinine treatment (25 to 30 grains daily). Of 8,788 hospital cases, 61 per cent. showed benign tertian parasites in their peripheral blood, 23 per cent. malignant subtertian, 16 per cent. both benign tertian and malignant subtertian parasites. The conclusions drawn from the study of these cases follow: 1. Neosalvarsan, salvarsan, neokharsivan, kharsivan, galy, administered intravenously, may be employed with safety in the treatment of all forms of malaria, provided the doses and methods recommended and the precautions to which attention is called be fully observed. 2. These preparations, in the doses recommended (neokharsivan, neosalvarsan, 0.45 gram; salvarsan, kharsivan, 0.3 gram; galy, 0.2 gram), exert a marked parasitocidal action on the benign tertian parasite, thick blood smears showing numerous parasites usually becoming negative within twenty-four to thirty-six hours. 3. These preparations have no definite parasitocidal action on any stage of the malignant subtertian parasite. When used in addition to quinine, the action of the latter is intensified and the progress toward recovery is much more rapid. 4. Generally speaking, the tonic effect of these preparations is well marked in all cases of malaria; anorexia, lassitude, and debility soon give way to a feeling of well-being, while tachycardia and shortness of breath, consequent upon anemia and cardiac dilatation, rapidly improve. Splenic enlargements disappear with remarkable rapidity. 5. The employment of these preparations is recommended, in addition to quinine treatment, in chronic resistant infections and malarial cachexia. Three or four injections at weekly intervals are recommended. Freedom from relapses cannot be promised even after numerous intravenous injections. In regard to the preparation of the solutions and technique of administration, the usual methods are followed in each case. 6. Soamin exhibits no parasitocidal action on the parasites of either benign tertian or malignant subtertian malaria. Its beneficial action is confined to the breaking down of the resistance of chronic infections to quinine. 7. Tartar emetic has no demonstrable effect on the sexual or asexual forms of the parasites of either benign tertian or malignant subtertian malaria, and exerts no influence on the clinical course of the disease. The most rapid and certain method of eradicating crescents from the finger blood is adequate quinine treatment (30 grains daily) and arsenic. 8. Inunctions of mercury and antimony ointment do not appear to exert any therapeutic action on malaria.

2. **The Circulation in Infectious Diseases.**—Garnett Nelson classifies the effects of infectious diseases on the circulation as follows: (1) Actual secondary infection of the muscle, valve, or membranes. (2) Hyaline degenerative changes in the muscle. (3) Degenerative arterial processes. (4) Heart strain and exhaustion from prolonged rapid action. (5) The more or less material changes in other organs due directly to a failing circulation. Certain controlling factors contribute especially to the frequency of these infections. These are particularly age and the specificity of certain germs. Three points are of especial importance in recognizing the circulatory complications, namely, persistent rapid pulse, a pulse whose rate is accelerated too much with too trifling a stimulus or exertion and fails to slow down promptly; the various forms of arrhythmia; and persistent low systolic pressure.

4. **Diarrhea Resulting from Biliary Insufficiency.**—William Howard Lewis, during a period of over three years' clinical service at the Mayo Clinic, encountered one case of extreme diarrhea of the "fatty" type which responded remarkably to the feeding of bile salts. At the Harbin Hospital (Rome, Ga.) four identical instances have been met with in a total of over 700 cases coming under observation. The discovery of this group within a period of eight months suggests that it is not an uncommon condition in that section of the country. Provisionally, for lack of a more definite term, the writer designates this condition as diarrhea due to biliary insufficiency.

Gazette des Praticiens.

November 15, 1920, xxvii, 498.

Relation of Intestinal Fermentation to Arteriosclerosis.—Lemoine has been impressed with two features in respect to arteriosclerosis. The first is the presence in arteriosclerotics of intestinal fermentation, while the second is the unusually large bulk of the stools. The first of these is known to the profession, but the second seems to be unknown. In well-marked arteriosclerotics the act of digestion seems to increase the malaise. This has led to the recommendation of small and frequent, nontoxic meals. Among the disturbances which one seeks to prevent by feeding are dyspnea, migrainous attacks, and insomnia. When these are present the intestinal functions will be found to be disturbed, and, the author believes, the consequence is the absorption of a poison which affects especially the nervous system. The presence in the urine of indican and urobilin in these subjects is an index of this absorption. In dieting these patients milk is freely used, and the author believes unwisely. It is taken in large quantities at times, and favors constipation and bloating. Given because of its supposed freedom from toxic matter, it leads to increased indican in the urine, and if there is albuminuria it aggravates that condition. The author replaces the milk and egg diet with a vegetarian regimen and with good results. The custom of giving white meats is also deprecated, these being equally harmful with the red, being difficult to digest and too rich in cholesterol. According to Chauffard this substance furnishes the makings for the deposits in the vascular walls.

Book Reviews.

PRACTICAL MASSAGE AND CORRECTIVE EXERCISES. By HARTVIG NISSEN. Fourth Revised Edition. Philadelphia: F. A. Davis Co., 1920.

In May, 1889, the author published his work on "Swedish Movement and Massage Treatment," which went through further editions, and he has also written at least two other books on the same subject before the first appearance of the present work in 1916. The fourth edition of the latter may therefore be said to sum up all his previous teaching with the experience of forty-five years of practice, over thirty of which seem to have been in the United States. The present volume contains among other addenda the most essential aspects of applied anatomy. The book is larger than at first sight appears, with 225 pages and 67 text figures. While much less in bulk than some of the pretentious works on massage it appears to cover the subject successfully, there being 28 chapters.

HANDBOOK OF PULMONARY TUBERCULOSIS. ITS DIAGNOSIS, PROGNOSIS, PREVENTION AND TREATMENT. By JEFFERSON DEMETRIUS GIBSON, M.D. Denver: The Denver Scientific Publishing Co., 1920.

The author's numerous honors published on the title page show manifold activities including membership in the regular and homeopathic national societies, physiotherapeutic and radiological national societies, etc., while he once filled the chair of physiology in a dental college. The cuts are chiefly of skiagrams of the chest. The work is thoroughly scientific and under the head of treatment nothing seems neglected which could benefit the patient, while stress is laid on the various electrical currents and on electrically generated ozone. Deep x-rays are used on deeply placed tuberculous lymph-nodes. Sero-immunization is also recommended but apparently less against the tubercle bacillus than the auxiliary microorganisms. The x-ray, however, is the better immunizer. The climatic problem is partly solved by the author's residence in Denver and but little is said under this head.

AUTO-EROTIC PHENOMENA IN ADOLESCENCE. By K. MENZIES. New York: Paul B. Hoeber, 1920.

This little volume, devoted to the psychology and psychopathology of onanism, has a preface by Dr. E. Jones, the psychoanalyst. The masturbator is considered from the viewpoint of the most modern psychopathology. In addition to the leaders in the realm of psychoanalysis, writers on sexual life like Havelock Ellis and those on sexual neuroses including the Americans Sturgis and Hühner, are freely quoted. The book hardly lends itself to review within a small compass but may be studied by those interested.

THE DUODENAL TUBE AND ITS POSSIBILITIES. By MAX EINHORN, M.D., Professor of Medicine in the New York Post-Graduate Medical School. Philadelphia and London: W. B. Saunders Co., 1920.

The author introduced his apparatus and technique to the profession in 1908. The method was known incidentally as catheterization of the duodenum, with the aim of testing directly the pancreatic function and secretion. Auxiliary dilatation of the pylorus was developed later. Swallowing the so-called duodenal bucket with its withdrawal string was introduced at the same period. The original tube was eventually supplied with a pump to facilitate aspiration and x-ray control was added. Since 1910 the technique has remained about the same, so that the author has had nearly ten years experience with the perfected technique. At the same period duodenal alimentation was also introduced. As an outgrowth of diagnostic dilatation of the pylorus, therapeutic dilatation has been developed. The duodenal tube has also been greatly lengthened in the attempt to reach the jejunum. This innovation is too recent to permit of positive generalizations.

AN EPITOME OF HYDROTHERAPY. By SIMON BARUCH, M.D., LL.D. Consulting Physician to Knickerbocker and Montefiori Hospitals. Philadelphia: W. B. Saunders Company, 1920.

In the absence of textbooks on the use of hydrotherapeutic measures, including the author's earlier and more comprehensive work, one can welcome the appearance

of this volume. Every practitioner should read it and study the application. Such measures as the cold compress and the wet sheets, with the various forms of sprays and douches, hot and cold, give a welcome addition to the weapons with which practitioners can fight disease. These methods teach the application of heat and cold and supply an active means of doing something to help the patients which both they and their friends insistently demand. This is a psychological effect which practitioners value highly. The chapter on Sunstroke is, perhaps, unnecessarily diffuse and that on installations might have been reserved for an architect. But, as the subtitle says, the book is intended for architects as well as for physicians and nurses. Hydrotherapy is valued in America and Dr. Baruch's previous work did much to place it in its proper position. To deal with inflammation and hyperpyrexia, hydrotherapy is invaluable: but, like all powerful remedial agents, it must be properly applied. Otherwise it will be justly neglected, as it has been in England. Dr. Baruch has done much to restore hydrotherapy to the position which it justly deserves.

THE ESSENTIALS OF HISTOLOGY, Descriptive and Practical, for the Use of Students by Sir EDWARD S. SCHÄFER, F.R.S., Professor of Physiology in the University of Edinburgh, formerly Jodrell Professor of Physiology in University College, London. Eleventh Edition. Philadelphia and New York: Lea and Febiger, 1920.

When a book has passed through eleven editions in thirty-five years, it is evident that it has a place of its own in the esteem of both teachers and students. This volume is not intended to enter into all the details of the science, but it is meant to give all essentials and to supply the directions for the microscopic examination of the tissues. All that experience has proved to be of value is included, while at the same time modifications can be included according to the experience of individual teachers. There are fifty separate lessons, each devised to last about three hours, and these are clear in instruction and include all details required for the essentials of the study of microscopic anatomy. It is quite one of the best books on the subject and has been carefully and regularly brought up to date.

THE SYMPATHETIC NERVOUS SYSTEM IN DISEASE. By W. LANGDON BROWN, M.A., M.D., F.R.C.P. (Lond.), Physician with charge of Outpatients, St. Bartholomew's Hospital, Physician to the Metropolitan Hospital. New York: Oxford University Press, American Branch, 1920.

This book is based on the Croonian Lectures before the Royal College of Physicians of London in 1918. Giving the main plan of the autonomic nervous system, the author tries to illustrate its relations to a few large groups of disease, such as those of the endocrine glands, some affections of the digestion and circulation, and glycosuria. The book deals also with the effort to understand the emotional response of the sympathetic nervous system and the influence of emotion on structure. Thus there is entry here for the study of the unconscious mind and the observation of the war-neuroses and their effects. The main thesis is that stimulation of the sympathetic and its coadjutors means the spending of reserves, with exhaustion as the result of a prolonged drain. The autonomic system acts as a whole, save when dissociation is one of the phenomena of disease and strain. The sympathetic system is not subject to, and must remain free from the control of the will. Our will can exercise restraint and we may deaden the emotion, but it cannot prevent the response, once evoked. Hence the author hopes to see the powers of tenacity and endurance evoked in the emotional response as a part of character developed by training. This sounds like the psychological mixture which the author expressly wishes to avoid. His clinical experience is so large that he deals completely with pathological processes in the effort to prove his thesis, and the result is a most suggestive volume which is entirely abreast of medical research. The sympathetic system is essentially the governor of function and the instant we are confronted with this we have to deal with emotions and their effects, both physiological and psychical.

Society Reports.

SOUTHERN SURGICAL ASSOCIATION.

Thirty-third Annual Meeting, Held at Hot Springs, Va., December 14, 15, and 16, 1920.

THE PRESIDENT, DR. WILLARD BARTLETT OF ST. LOUIS, MO., IN THE CHAIR.

(Concluded from page 244.)

Life Expectancy Following Radical Amputation for Cancer of the Breast, Based on a Clinical and Pathological Study of 218 Cases.—Drs. W. E. SISTRUNK and WILLIAM CARPENTER MACCARTY of Rochester, Minn., found by studying the results obtained in 218 cases that 51.8 per cent. of the patients operated on, one of each two patients were living three years after operation. Seventy-five and six-tenths per cent. of the patients in whom the glands were not involved, three of each four patients were living at the end of three years, and 35.6 per cent. of the patients with glandular involvement, about one of each three patients, were alive at the end of three years. At the end of five years 39 per cent. of the patients operated on, about two of each five patients, were alive; 65.1 per cent. of the patients in whom the glands were not involved, about six of each ten patients, were alive five years after operation, and 21.9 per cent. of the patients with glandular involvement, about one of each five patients, were alive at the end of five years. Thirty-six and seven-tenths per cent. of the 218 patients operated on, about one of each three patients, was alive from five to eight years after operation; 63.9 per cent. of these died within five years after operation. Age seemed to have a definite bearing on the results to be expected following operation; 41.7 per cent. of the patients over fifty years of age were alive from five to eight years after operation, while only 31.8 per cent. of those under fifty had lived for a corresponding time. The immediate hospital mortality from operation for cancer of the breast was less than one-half of 1 per cent. In their experience the prognosis had not been affected by the complete removal of small growths for microscopical diagnosis before the radical operation was performed. When local recurrences were found following operation metastases were demonstrated in other regions in 60.9 per cent. of the cases, six of each ten patients. In their experience nearly all patients who developed a recurrence of the malignancy following operation died from the disease.

The Diagnosis of Breast Lesions at the Exploratory Incision.—Dr. JOSEPH C. BLOODGOOD of Baltimore said the propaganda of education on cancer had had its effect. Women conscious of trouble in a breast now sought advice quickly. His records showed a rapidly increasing large number of patients who, after examination, had apparently no discoverable local condition in which experience taught that operation was necessary. The per cent. of benign lesions had rapidly increased. For these, when exploration had ruled out cancer, local removal was sufficient. Far more important, the number of cancers of the breast in the early stage was largely increased. In the majority of these the diagnosis could only be made at the exploratory incision, and the best permanent results were obtained by the immediate complete operation after the exploratory incision had revealed the cancer. The mistake that should not be made was the incomplete operation for cancer. If this was possible in one clinic, it should be possible in others. The records of the Surgical Pathological Laboratory of the Johns Hopkins Hospital demonstrated that since 1889, a period of 31 years, the mistake of performing an incomplete operation for cancer of the breast had been made five times by Dr. Halsted and the surgeons operating or trained in his clinic, and this mistake had been made but once since 1900. The mistake of performing the complete operation for cancer and then, after pathological examination and reexamination, coming to the conclusion that the lesion of the breast was not malignant, was the mistake that would be made and had been made in a varying per cent. of cases by the surgeons in this group. Up to 1910 it averaged about 10 per cent. From 1910 to 1915, associated with increasing number of very

early lesions, the per cent. increased to 20. The actual per cent. from 1915 to 1920 had not yet been worked out. The avoidance of the fatal mistake should be the first business of the surgeon, because this increased the probability of death from cancer. In this very early stage the probability of a cure should be 80 or more per cent. The avoidance of the second mistake diminished the number of women from whom one or both breasts were removed unnecessarily. There was no unsurmountable obstacle to any surgeon and his associates to develop the art and science which would enable him to recognize breast lesions in which operation was not indicated and for which, after the exploratory incision, excision of the local lesion was sufficient, bearing in mind that when in doubt the complete operation for cancer should be performed. The first requirements of surgeons today was to eliminate the mistake of performing an incomplete operation for cancer. A follow-up system would reveal this, and it was practically the only check. When cancer of the breast was incompletely removed there was rapid local recurrence, with the rarest exceptions within one year. When the breast only was removed for cancer there might be a longer period before the involved axillary glands became palpable. It made no difference how the diagnosis was made at the exploratory incision. One might cut into the tumor and inspect it; one might cut the local lesion for inspection. The surgeon might train himself to be his own pathologist, or he might associate with him a trained pathologist. The second point was far more important as to whether the final decision should rest upon the frozen section only. His own studies, which began in association with Dr. Halsted in 1892, agreed with his view at that early time, that in the vast majority of lesions of the breast the gross inspection of the local lesion was as important as the examination of the frozen section, and in many, especially in certain benign lesions, a more reliable conclusion could be reached. When cancer was distinct in the gross it was equally distinct in the section, but many tumors, especially the encapsulated benign adenoma and many of the cysts, had in the gross almost pathognomonic signs of benignancy, while frozen sections revealed pictures difficult to distinguish from possible early malignancy. This conclusion had been confirmed by submitting many sections to a large number of pathologists. He had in his laboratory numerous distinctly encapsulated adenomas of different types. The operator had removed the tumor only, basing his conclusions on the encapsulation. There had been no recurrence and these patients had been followed from recent periods to twenty-eight years. Yet, when sections from such tumors were submitted to pathologists, a diagnosis of malignancy or "suspicious of malignancy" had been made in a varying per cent. of the cases. At the recent meeting of the American Medical Association in New Orleans, he described the blue-domed cyst as a distinct gross entity, sufficient to indicate the removal of the cyst only. In this group sections from the wall of the cyst and surrounding breast submitted to a group of pathologists resulted in the same conflicting reports. The same was also true of the cyst containing a benign papilloma, of the non-encapsulated diffuse areas due to tubercular mastitis without abscess or caseation, of chronic mastitis in lactation without gross pus formation, of the rare cases of chronic interstitial mastitis not associated with lactation, of the nonencapsulated areas of lipoma containing inflammatory areas. Now that women were seeking advice early after the first discovery of trouble in one or both breasts, the actual number of women who might lose one or both breasts unnecessarily was becoming very large, and must be seriously considered. The evidence that they should have one or both breasts removed to protect them from cancer was no greater than in any other woman of the same age who was unaware of any trouble in the breast, and for this reason did not come under observation. Unfortunately, at the present time there was a difference of opinion apparently among surgeons of large experience, first, as to the indications for operation. For example, in discharge from the nipple when there was no palpable lump. The view Dean Lewis and himself took was that operation was not indicated. Others thought that this discharge was a sign of a precancerous lesion and that the breast should be removed. Second, what was a

palpable lump? His experience taught him that some surgeons had failed to improve their tactile sense to keep up with the demands for distinguishing a lump which was really not an indication for operation. What should be the surgeon's attitude when multiple indefinite lumps were found in both breasts? There was also a difference of opinion as to the methods of exploratory incision and the most reliable way of distinguishing a benign from a malignant lesion. The whole question of chronic cystic mastitis and its relation to malignant disease needed revision. From his studies the danger of cancer had been exaggerated. These questions would be fully brought out in an article to be published in the *Archives of Surgery* on "Chronic Cystic Mastitis" and in a second article on "Discharge of Blood from the Nipple."

Dr. WILLIAM CARPENTER MACCARTY of Rochester, Minn., said that the surgeon was the only man who could show us cells as they really were, and he was the only man who was doing it. As to the early diagnosis of cancer, if we as clinicians would educate people to come to us in what we called the precancerous stage or condition, we must be able to differentiate a precancerous condition from one that was not precancerous. At the present time, in the Mayo Laboratory, 20 per cent of all the tumors of the breast must, of necessity be diagnosed by the microscope, which meant 80 per cent. only could be possibly diagnosed grossly, and he might say 80 per cent. of these figures was the percentage of gross diagnostic efficiency in the hands of individuals who had done nothing else for the last fifteen years but to see and examine pathological material. If the surgeon, who only occasionally saw these cases, possessed that diagnostic efficiency, he should be greatly surprised. That percentage ten years from now would probably be forty, because the longer this question was studied the smaller the lesions became, and today in the Mayo Laboratory they studied every breast where there was the slightest suspicion, where the tumor was not so that one could immediately see it five or six feet away. These specimens were studied with the microscope to improve diagnostic efficiency. What did that mean? It meant we were picking up much smaller carcinomata than we had ever picked up before, and he knew in his own experience he had missed many carcinomata of the breast because they were small, and he relied absolutely on gross diagnosis.

Dr. HENRY O. MARCY of Boston said that while he was in Edinburgh many, many years ago, Dr. Bennett declared to him his conviction that cancer was first local and probably was disseminated through the lymphatics, and that as a consequence it was of the greatest importance to operate early with great care in order to remove all glandular enlargements. The general teaching up to this time had been that cancer was a constitutional disease, and that operation at the best was only a palliative measure of relief. Convinced of the correctness of Dr. Bennett's opinion, he had since surgically fought cancer as a fire department did fire, with the conviction of having saved many lives. In one of his earlier studies he made cultures from material carefully taken from mammary growths. It was not difficult to differentiate a coccus which in repeated cultures bred true, but he failed to reproduce them by inoculation in animals. At this time he became aware of the sad experience of one of the younger members of the profession, who had developed a malignant growth of the face requiring frequent dressings. On one of these occasions unintentionally he rubbed his own face and inoculated a small abrasion. This was thought little of until later, when it spread rapidly and cost him his life prior to that of his patient.

Dr. J. SHELTON HORSLEY of Richmond, Va., said that if cancer was chiefly, if not entirely, caused by the contact of manure with tissue, as pointed out by Dr. Ochsner, it would be difficult to explain why cancer in the rectum, which was in contact with autogenous manure, was not universally fatal. It was also difficult to explain why it was that cancer in the stomach appeared to be much more common than cancer of the rectum. The contents of the stomach under normal conditions were practically sterile. If the general types of cancer or malignant tumors were included, it would be difficult to explain why sarcoma of bone was not due to tissue contact with manure. It was also true

that carcinoma of the breast occurred in a locality which certainly in the male was not ordinarily exposed to the atmosphere and in which to some extent it was protected. It was certainly far more protected than the face. It was also true, as statistics showed, that cancer of the buccal surfaces in the Indian was much more common even without the use of the pipe. Cancer following the chewing of the betel nut or smoking a pipe was a comparatively sterile condition.

Dr. CHARLES H. MAYO of Rochester, Minn., said that he was very glad the ladies were present during the presentation of this symposium on cancer, because he fully believed the presence of women would do more to disseminate such knowledge among the people than this entire body of surgeons. If communities were educated in regard to certain things, people would not only ask for them but demand them. Much of the work that had been done to advance medicine in the past had been accomplished by educating the people. That was the reason so much had been accomplished with tuberculosis and with the question of the prevention of infectious diseases, and now came the question of cancer. As had been shown, we had increased wonderfully in our ability to control cancer because the people had been educated to come early. Personally, if he had cancer of the breast, he would rather have a poor surgeon operate on him early than the best surgeon possible to operate on him late.

Dr. JOHN G. CLARK of Philadelphia said that where a carcinoma of the uterus had been taken out, one might still find carcinoma cells. Recently he had an interesting case along the line of curability of these cases. Some three and a half years ago a woman presented herself with carcinoma of the vagina, which was totally inoperable. She was sent in for radiumization by Dr. Stewart, of Wilkes-Barre, Pa. He gave a light dosage of radium because he was afraid of producing a fistula in the bladder or rectum. For three months she was very ill in bed. A year from that time, very much to his surprise, she came to see him at the request of Dr. Stewart, and in the center of this carcinoma there were very definite carcinoma nests. He was afraid to apply radium further. She went home. She returned this fall. He took out from that identical spot more tissue, had it examined, and found it absolutely free from carcinoma. In other words, it was the strongest argument he had found in favor of the use of radium. However, he took the same position that had been enunciated here today, namely, that if a case was still operable, he would operate, but he was finding fewer and fewer operable cases.

Dr. R. C. COFFEY of Portland, Ore., said, with regard to the transportation of cancer cells during operation, that within the past month he had had four cancer growths in abdominal wounds which he made personally within the last year in cases in which the growth had not occurred so far at the point from which the cancer was removed. This must be an extraordinary series but this occurred in three of them that were at the hospital at this time for treatment. In each of these cases it was during operation that the cancer growth was broken down. One was a cancer of the stomach attached to the pancreas, but there was no evidence at the present time, which was nearly a year ago, of involvement or recurrence in the stomach. In another case the cancer was located in the sigmoid flexure. He only removed a portion and left a colostomy opening. At the point of removal there was no recurrence in the intestine, but there was a recurrence in the wound about two inches below the point where the intestine was brought out. Another was a cancer of the uterus in which the organ was removed, the abdominal wall being infected, but no recurrence at the point of operation. Another was a case of extensive malignant cyst which he was unable to remove because of its attachments to other organs. He opened and packed with gauze and applied 100 milligrams of radium. There was no recurrence of the cyst, but an extensive growth appeared in the abdominal wound.

Dr. THOMAS S. CULLEN of Baltimore, Md., said that a number of years ago, while he was collecting statistics of cancer of the breast, he felt very gloomy as to the outlook. Through popular articles written by Samuel Hopkins Adams on the subject, after visiting Baltimore, Chicago, and Rochester, and analyzing the

subject as thoroughly as he could, great good was accomplished. These articles appeared in the *Ladies Home Journal* and other magazines and were copied in many other journals. As an example, a committee of the American Medical Association, as a result of the *Ladies Home Journal* article, learned from Dr. LeGrand Guerry, Columbia, S. C., that he had received in five weeks six early cases of cancer of various organs. The medical profession should in every way support the excellent work of the American Society for the Control of Cancer.

Dr. E. G. JONES of Atlanta, Ga., stated that if the malignant condition was on the left side instead of the right, of those abdominal aortic lymphatic glands which received drainage from the various viscera, only those which lay on the aortic side received kidney drainage. These same glands likewise received drainage from the inguinal glands, and from the sex glands and from the abdominal parietes. It was a source of comfort for surgeons to know this.

Dr. WILLIAM B. COLEY of New York City believed with Dr. Mayo that many of these tumors seemingly benign were potentially malignant. If we took sarcoma, we knew 50 per cent. of them had an antecedent local trauma. We had there something developed which was exactly in harmony with what we knew developed in disease of known germ origin, like tuberculosis. There was a large number of cases of bone tuberculosis that started with antecedent trauma.

Relaxation of the Vaginal Outlet; Is the Obstetrician Responsible?—Dr. LUCIUS E. BURCH of Nashville, Tenn., stated that relaxation of the vaginal outlet was caused by overstretching of the levator ani muscle and a lack of tone following labor. It was impossible for the obstetrician to determine at labor whether the muscle would regain its normal function or not. All lacerations following labor should be immediately repaired for the purpose of preventing sepsis, remembering that it would not prevent relaxation if the levator was overstretched. The condition was easily cured at secondary operation by bringing together the overstretched muscle in the median line by interrupted sutures.

Kraurosis Vulvæ and Inguinal Adenitis.—Dr. FRANCIS REDER of St. Louis stated that in kraurosis the histological changes were situated in the dermis and usually presented a general atrophic process involving the entire vulva, with marked contraction of the vaginal orifice. Not infrequently the glans clitoridis and the labia minora had disappeared and the ostium vaginae had become narrowed to such an extent that an attempt to introduce the index finger, if at all possible, was the causation of great pain. Some cases frequently showed atrophy of the mons veneris with complete alopecia. A patient afflicted with this disease was often a great sufferer, and not only was coitus very painful, but the itching and burning were frequently almost unbearable. The assumption that the pathological process of kraurosis vulvæ could be accepted as an inherent primary disease appeared to him still strongly lacking in corroborative evidence. A critical analysis of the clinical picture of pruritus and leucoplacic vulvitis disclosed so many features in common with kraurosis that the inference could be made that kraurosis was an expression of a severe degree of these lesions, and that without pruritus and leucoplacic vulvitis there would be no kraurosis. Some investigators recommended in the more pronounced cases of kraurosis with dyspareunia an incision widening the vaginal outlet. He would advise against this procedure as it had little to recommend it. It had no beneficial influence upon the condition, and did not prevent a subsequent contraction of the ostium. Reverting to the two cases with infiltrated cancerous ulcers and metastases in the inguinal glands, a radical excision was made in each instance. The operation pertaining to the inguinal dissection required a technique of much delicacy and was somewhat severe. An operation of this character could not be a satisfactory one unless all inguinal glands were removed, especially important ones situated deeply around the femoral vessels. Such a dissection required the division of Poupart's ligament. The relief these patients were free from any of their former suffering, with no evidence of any recurrence. The operations were performed respectively nine and eleven months ago.

An Analytical Study of 50 Cases of Ureteral Stricture and Pyelitis.—Dr. J. N. BAKER of Montgomery, Ala., stated that of the 50 cases, 39, or 78 per cent., were unilateral; 26, or 52 per cent., occurred on the right side, and 13, or 25 per cent., on the left; 11 of the 50, or 22 per cent., were bilateral. It would thus be seen that the ratio of incidence of the right sided lesion as compared with the left was as 2 to 1, and that of bilateral to unilateral the incidence was as 1 to 4.5, approximately. Points of importance in differentiating between these two lesions were the following: (1) Careful microscopic examination of a catheterized specimen of urine. (2) Absence of marked right-sided abdominal rigidity when the lesion was retroperitoneal. The acutely inflamed appendix rarely failed to produce demonstrable rigidity in the lower right quadrant. (3) Hyperpyrexia pointed to infection within the kidney pelvis, rarely to the appendix. (4) The Murphy sequence of onset of symptoms when the lesion was appendiceal, that is, pain, nausea, vomiting, elevation of temperature. In 49, or 98 per cent., an appreciable obstruction could be demonstrated at some point within the ureter above its entrance into the bladder by means of the wax bulb implanted upon the catheter. In 35, or 70 per cent., the obstruction was from 3 cm. to 6 cm. above the bladder opening or within the broad ligament area. In 12, or 28 per cent., the obstruction occurred from 9 to 12 cm. at or near the pelvic brim. The only case in the series failing to reveal ureteral obstruction was that of a child of 13 with bilateral pyelitis. The frequent occurrence of symptom-producing lesions of the urinary tract in the female demanded an exact diagnostic study before resorting to surgery. These lesions were largely dependent upon infections of a hematogenous origin, the primary foci of which must be diligently sought out and removed before permanency of cure could be hoped for. Both clinical experience and experimental studies tended to incriminate tonsils and teeth as the chief offenders. Not only were strictured conditions of the ureter of more frequent occurrence than had been generally supposed, but their presence, by mechanically impeding drainage, constituted an important factor which must be reckoned with in the effort to clear away subacute or chronic infections of the urinary tract.

The Surgical Treatment of Acute Pelvic Infections in Women.—Dr. F. G. DUBOSE of Selma, Ala., said that failure to remove the focus of infection rendered the operation relatively valueless; the source remaining, it was to be expected that the fury of the infection would increase and the involvement of contiguous structures and remote metastases would most certainly result. Pelvic debridement was urged in that pyogenic membranes with infected tubes, uterus and ovaries should be removed. Gauze packs over denuded pelvic surfaces to stop oozing and to hinder capillary absorption, thus limiting further extension of the infection. Eroded or denuded intestinal surfaces were peritonized or overlaid with the omentum. Rubber dam covered the gauze packs and the pelvic operative field, minimized the formation of adhesions, and drained freely and continuously. The gauze and rubber ends were brought out through the lower end of the incision and transfixed with a safety pin. The abdominal incision was closed in layers and snugly around the drains. The dressings over the incision should be voluminous and changed as often as soiled to keep up capillary suction. The results which had followed this plan were: The saving of life, shortening to a marked degree the post-operative period of recovery, the elimination of a prolonged morbidity, the relatively earlier restoration to health, and the resumption of the normal activities of the woman.

An Estimate of the Value of Local Anesthesia in the Surgery of To-day.—Dr. WILLARD BARTLETT of St. Louis read a paper of which the following were the conclusions: "(1) It is to be definitely understood that ether by the drop method is the anesthetic of choice in our clinic for major surgery in general, and local anesthesia in some form for minor surgery. But we go much further than this, hence an attempt has been made in this address to deal with the large number of special considerations, which do not fall into either one of the above-mentioned classes. (2) One must always keep in mind that local anesthesia has definite limits which

are not to be transgressed. I have attempted to make many of them clear. (3) I believe that with increasing experience and better training we shall some day have to establish indications for general anesthesia rather than for local, as is the common experience today. It will then seem no more reasonable to anesthetize the entire organism for a strictly local operation on it than it does at the present time to bind or splint the entire body for an injury to an extremity. (4) Surely no one will advocate the use of local anesthesia to the point of interfering with the smooth and rapid conduct of a surgical procedure. (5) It may be safely stated that the anesthetization should never be larger than the operation. For example, one should not under ordinary circumstances attempt a radical breast operation, nor, it seems to me, any one of the larger abdominal procedures which involve both sides of the midline, under local anesthesia alone. (6) The operator will have to train himself especially for this work if he expects to be successful in it, although in a busy clinic it is unquestionably the correct plan to have one associate who has this phase of surgery wholly in his hands. (7) There is, to my thinking, a very definite field for the local anesthetist. I am sure that such an individual should play a role similar to that which is well known in general anesthesia. His services ought to be in demand by the surgeon who makes only an occasional use of these methods, or by one who is not temperamentally suited to the acquirement of them. I have been so fortunate as to profit by the accomplishments of my assistants, Dr. Samuel F. Wenneman and Dr. William Murray Winn, to whom I am indebted for most of my local anesthetics in recent years, to say nothing of much of the enthusiasm which I have acquired for this subject."

Laryngeal Function in Thyroid Cases.—Dr. E. S. JUDD of Rochester, Minn., thought it might be said in conclusion that (1) the functional results following thyroidectomy as concerned both phonation and respiration were extremely good; (2) the disturbance which sometimes followed immediately after the operation was temporary, and normal function would be restored in from a few days to a few weeks, and (3) there was a very small group of patients who, following thyroidectomy, had a bilateral abductor disturbance which was slow in onset, but was very persistent. He had been unable to work out the cause of this condition, but believed that it might be due to the contraction of a scar, to a peculiar type of trauma to the nerve, or to some form of toxemia.

Ulcer of the Jejunum Following Gastroenterostomy.—Dr. J. SHELTON HORSLEY of Richmond, Va., said that the cause of jejunal ulcer after gastroenterostomy was the pouring of acid gastric juice directly into the jejunum, which was physiologically fitted for only alkaline contents. He called attention to the fact that similar changes in other viscera produced marked symptoms, such as the changing of urine to an alkaline medium, producing cystitis, and even a great reduction in the acidity of the gastric juice gave rise to symptoms. Doubtless many ulcers after gastroenterostomy did not come to operation, and for every jejunal ulcer that was formed there were probably many instances of irritation and hyperemia of the jejunum which were not sufficiently severe to produce ulcer and yet did cause symptoms. The generally accepted treatment of jejunal ulcer after gastroenterostomy was to disconnect the gastroenterostomy and do a pyloroplasty. If a pyloroplasty had been done in the first instance, the jejunal ulcer would have been avoided. A jejunal ulcer that occurred on the mesenteric border of the jejunum opposite the gastroenterostomy was reported. The technique of his pyloroplasty was referred to and slight changes in the technique of the previously reported operation were noted. There was a brief report of cases done by his pyloroplasty. Gastroenterostomy was indicated when there was complete stenosis of the pylorus, where the results after gastroenterostomy were always satisfactory. The reason for this was discussed. Gastroenterostomy was also indicated when there was extensive leukocytic infiltration around a subacute perforation of the ulcer, and, of course, where there was inoperable carcinoma. Attention was called to the fact that the good results of pyloroplasty as compared with gastroenterostomy only showed up with the increase of time.

Adhesions about the pyloroplasty as from a diseased gall-bladder caused more symptoms than when a gastroenterostomy was done. For this reason care must be taken to remove a diseased or adherent gall-bladder to cover the raw surface with omentum or fat, and to have the patient lie on his left side as much as possible for several days after operation.

Surgery of the Gall Bladder.—Dr. T. CASEY WITHERSPOON of Butte, Mont., believed it was fair to state that, in the early period, when no prohibitive coincident malady existed, the removal of the gall-bladder was not only justifiable but should be done by the surgeon. In the later period when gallstones or chronic inflammation obstructed the flow of bile there could still be no question as to the advisability of a radical procedure, conjoined always with careful exploration of the common duct insuring its patulousness. In conclusion, the chief plea which he wished to make was for early operation, one which was not only made easier and safer for the patient by reason of there being no complicating factors, but one which would often save from many distressing ailments, local and remote, which could not be fully relieved if the disease was allowed to run on in the blind hope that medical treatment could bring about a cure.

Report of a Large Ovarian Cyst in an Infant Seven Months of Age.—Dr. WILLIAM A. DOWNES of New York City said that the report of a single case of ovarian cyst in an infant was presented partly to call attention to an unusual condition, but more especially for the purpose of making a plea for earlier operative interference in the surgical diseases of infants and children. In the case here reported a swelling of the abdomen was noted at birth which steadily increased in size, but it was not until the seventh month that a surgeon was consulted. The history of the case was as follows: G. P., born February 13, 1920. Admitted to the Babies' Hospital September 24, 1920, with a history of enlargement of the abdomen, present since birth. Full term infant, normal delivery, weight nine and a half pounds. During the first three months the baby suffered from colic, and occasional loose stools with mucus. Took feedings well and did not vomit. General condition continued good and infant seemed well in every way except for the increasing enlargement of the abdomen. The abdominal distention was thought to be due to Hirschsprung's disease until x-ray examination demonstrated a normal intestinal tract. Examination on admission to the hospital showed the patient to be well developed and well nourished. Bright, not fretful, and apparently comfortable in spite of the enormously distended abdomen. Chest measured 15 inches, abdomen 24 inches, length 25 inches. Weight 17 pounds. Abdomen symmetrically enlarged. A definite fluid wave and fluctuation easily made out. Dullness extended over entire abdomen and into the flanks. On rectal examination a pedicle could be felt anteriorly and to the left. Antioperative diagnosis, ovarian cyst. Operation September 24, 1920, lower right rectus incision. No free fluid in peritoneal cavity. Large moderately thick-walled cyst. Trochar introduced and two and a half liters of clear straw-colored fluid withdrawn. Pedicle size of little finger springing from left cornu of uterus ligated with No. 1 plain catgut. Right tube and ovary normal. Abdomen closed in usual way. Convalescence uninterrupted. Discharged from the hospital October 7, 1920, cured. Pathological examination by Dr. Martha Wollstein showed simple ovarian cyst. No evidence of malignancy. December 3, 1920, mother reported that the baby appeared normal in every way and was gaining in weight rapidly.

Gastric and Duodenal Ulcer.—Dr. CHARLES H. MAYO of Rochester, Minn., believed that the accident of peptic ulcer was rare and represented but a fraction of 1 per cent. of the findings of general necropsies. In the aggregate, however, the condition occurred in thousands of persons, many of whom apparently never suffered from symptoms of gastric origin; others did not appreciate their symptoms. When acute and chronic bleeding, perforation, and mechanical obstruction were the main diagnostic points of ulcer, hemorrhage was relied on in making the diagnosis. These symptoms lost their importance as diagnostic ability improved. Peptic ulcer was more common in males than in females, the proportion being 3 to 1. The proportion of gastric to

duodenal ulcer was approximately 1 to 4, as shown by reports from the Mayo Clinic, where from January 1, 1906, to January 1, 1920, operations were performed on 1,191 patients with gastric ulcer and on 4,532 patients with duodenal ulcer. In a series of 638 patients with gastric ulcer observed in a five-year period, 28 had multiple ulcers. Peptic ulcer was undoubtedly developed by a combination of local chemical effects, possibly causing prolonged vessel spasm or claudication, a counterpart of Raynaud's disease or scleroderma, or by direct interference with the circulation through infarction emboli of bacteria, chemically and mechanically active in the tissues and thereby lowering the local resistance to the action of digestive fluids. The relation of pepsin and acid had always been recognized as associated with the development of these so-called peptic ulcers. The medical treatment of gastric ulcer in an exacerbation during waking hours was directed toward controlling and lowering the acidity by dilution or neutralization of gastric contents at regular periods. Some surgeons performed gastroenterostomies because of symptoms, as, for instance, digestive reflexes, abdominal and even spinal, without positively determining the presence of ulcer. To the discredit of surgery it was necessary in a number of cases to cut off and close the gastroenterostomy which was made, although no ulcer was present. The surgeon, on the other hand, appeared to discredit the internist, as he never saw an ulcer in the early stage unless it had perforated or was causing hemorrhage. He thus might exaggerate the danger of ulcer. Although the patients might have passed years in the active care and treatment of their stomachs, the gastric trouble was reflex in origin. In a study of the results of 647 operations performed in the Mayo Clinic on 738 patients with calloused ulcer of the stomach from July 1, 1914, to July 1, 1919, the average mortality was 3.2 per cent.; there was more than double the average mortality in 2,734 operations performed in the same period on 2,720 patients with duodenal ulcer. Many ulcers believed to be benign and excised showed the presence of a carcinoma in a limited area of the margin. Balfour, on the theory that malignant cells were much more vulnerable to heat than normal cells, suggested and developed a slow destruction of ulcer by perforation with the cautery and immediate closure and gastroenterostomy. In 89 operations performed in the Mayo Clinic for hour-glass stomach the operative mortality was 7.4 per cent. The sleeve resection of the central portion of the stomach, usually with gastroenterostomy, was performed. If there was recurrence, the lower half was removed at the second operation, the narrowed proximal portion being united to the jejunum, and sometimes to the duodenum. As a rule, the same type of union of the stomach with the duodenal end or the jejunum was made for extensive ulceration and thickening and for local cancer in the pyloric region after resection of the stomach. Gastrojejunal ulcer was an unfortunate condition which occurred in a small percentage of patients who had been primarily relieved by gastroenterostomy. The present small percentage of these cases could be markedly reduced by avoiding the use of permanent suture material for the brief period demanded in the ordinary case of gastroenterostomy. Graham, in an investigation of 438 cases of duodenal ulcer, found that from the standpoint of the patient 70 per cent. who survived the operation considered themselves well following gastroenterostomy, 27 per cent. improved, and 3 per cent. unimproved. The future condition and length of life of patients with peptic ulcer were problems recognized by insurance companies in considering the applications of those who had had operations for ulcer. Hunter, actuary of the New York Life Insurance Company, in an investigation at the Mayo Clinic of the results of operation in a large series of cases of gastric and duodenal ulcers found that the average death rate for the four-year period after operation in patients with gastric ulcers was slightly more than three times the normal, while in patients with duodenal ulcer it was, if anything, slightly less than normal. The series consisted of 2,431 patients, all but 108 of whom were traced.

Appendicitis and the Rubber Glove.—Dr. ROBERT T. MORRIS of New York City said that in the third or pathological era of surgery the rubber glove had ap-

peared and had become established in the ritual of surgical work. The rubber glove lessened the tactile sense and stood in the way of some of the nearest work which was sometimes desirable in appendicitis with adhesions. More bacteria fell into a large incision from the air than were carried in by a properly prepared hand minus the glove. Working through short incisions by the sense of touch in cases suitable for that method of treatment belonged to the fourth or physiological era of surgery in which the patient was given home rule; in other words, turned over to his own protective resources with the least degree of surgery which would suffice for the purposes of the moment. He believed that the rubber glove had its place in standardized surgery, but a loophole must be left in hospital rules in cases in which hospital authorities in their commendable zeal for standardization made the wearing of rubber gloves obligatory in all operative work, otherwise hospital rules would stand in the way of the best surgery in some cases.

Local Anesthesia in Kidney Surgery.—Dr. CARROLL W. ALLEN of New Orleans said that in regard to the technique of local anesthesia in kidney operations, the patient was laid on the table in the proper position, but the table was not broken, or the Lillenthal bridge raised, until the kidney was ready to be exposed, as this position, if maintained too long, might be uncomfortable. A skin wheal was made about the center of the proposed incision, through which a long needle fitted on a large syringe was entered; this was passed upward slowly under the skin along the proposed line of incision, injecting as the needle was advanced to the interval between the eleventh and twelfth ribs. The needle was next partly withdrawn and directed downward along the proposed line of incision beneath the skin infiltrating the entire distance down to the crest of the ilium. The needle was then directed downward from the skin surface to reach the lumbar fascia, which was recognized as the first plane of resistance in the deeper parts. The attempt should be made to reach this fascia just at the outer margin of the quadratus lumborum muscle. This was pierced by the needle at about three points an inch or more apart and the tissues beneath the fascia infiltrated. Having completed the above injections, the skin was next infiltrated intradermally with a small needle and syringe. This was purposely left to the last and this slight interval, after the deep injections had been made, allowed them a slightly longer time to saturate the tissues. This skin injection could be omitted if the subcutaneous injection had been made just beneath the skin, but if this was done in stout subjects an additional injection should be made in the subcutaneous tissues at a slightly lower level. The incision was made next the entire length of the field and carried down to the lumbar fascia. The twelfth nerve was then injected high up, just under the twelfth rib. This nerve was a large trunk, larger than the other intercostals, about one-eighth of an inch in diameter, and ran obliquely downward across the field. At two inches from the spinous process of the vertebrae it lay about one inch below the rib; from this point it followed the outer edge of the quadratus lumborum lying in close contact to it beneath the lumbar fascia as far down as the crest of the ilium. It should be injected high up, proximal to the field. The long needle was next passed inward through the lumbar fascia and the cellular tissue and fat around the kidney lightly infiltrated. All bleeding points were ligated, the table broken or the bridge raised. This interval allowed time for the last made injections to diffuse. The lumbar fascia was divided close to the edge of the quadratus lumborum, the twelfth dorsal nerve was exposed and should be protected. The finger was slipped in over the surface of the quadratus muscle toward the vertebral column and the long needle passed in alongside of it, and the tissues just to the side of the vertebrae and in front of the transverse processes were lightly infiltrated at three or four points up and down the spine. It was here the rami communicantes which came forward from the spinal nerves joined the sympathetic chain alongside of the vertebrae. These nerves carried sensory fibers to the abdominal plexuses. The bodies of the vertebrae were easily palpated and the structures lying on it, the aorta and vena cava. The cellular tissue and fat around the kidneys was then opened and

delivered into the wound. If the kidney was to be removed, bisected, or the operation involved its hilum, a light infiltration was necessary around the vessels, but this was not needed if the operation was limited to its cortex. This additional infiltration was necessary as all arteries carried sensory nerve fibers. On the renal arteries they came from the plexus on the aorta. This completed the technique, and when done in a methodical way was quite quickly executed.

The Semi-Centennial of the Introduction of Antiseptic Surgery in America.—Dr. HENRY O. MARCY of Boston recounted in an interesting manner the early history of antiseptic surgery and his first acquaintance with Lister, who explained to him in a painstaking manner his methods, with a demonstration of the results of his operative procedures. At that time the speaker was impressed with two cases of resection of the elbow joint in strumous children, probably tuberculous infection. The wounds were without pain or swelling, and the little unfortunate patients showed slight evidence of suffering. At about the same time he became acquainted with Keith and Sir Spencer Wells, who laid great stress on strict cleanliness in surgery. After speaking of the work of other eminent surgeons of Edinburgh and London he had seen, the essayist reviewed the work of eminent American surgeons at that time, particularly that of Van Buren, Stephen Smith, Marion Sims, T. Gaillard Thomas, Henry J. Bigelow, etc.

Postgraduate Medical Study in France.—Dr. SAMUEL LLOYD of New York City contributed a paper on this subject in which he stated that every year a considerable number of the students at the New York Postgraduate School came to him for advice in regard to where they should go in Europe to pursue their investigations. In the past he had been sending them to the different clinics in Germany and Austria. He was hoping that in the future it might be possible for him to advise them to go to Paris, and that he might be able to place before them a comprehensive scheme together with definite information in regard to questions of cost and of time required. A short time ago he received a synopsis of the courses which had now been organized for postgraduate work. These courses were given in considerable detail.

Preliminary Ligation of the Common Iliac Artery in Hip Joint Exarticulation.—Dr. FRED W. BAILEY of St. Louis reported a case of preliminary ligation of common iliac artery in hip joint exarticulation. In reviewing the literature the remarkable persistence of Morand, of France, was referred to. In 1729, fifty years before hip joint amputation was considered safe enough to put into actual practice by Kerr, of Southampton, Morand made repeated efforts before the Royal Academy of Surgery, of Paris, to secure recognition of his idea, that exarticulation was possible without immediate death. He died before Kerr's original effort, but lived to see his suggestion accepted by the Academy. Attention was called to the successful application of this surgical step at the hands of Larrey, the Emperor's noted surgeon, during the Napoleonic period, and of the final adoption of his joint disarticulation as a justifiable procedure where removal of the limb was indicated. The unusually high mortality, nevertheless, ranging from 90 per cent. to 55 per cent., was attributed to shock, hemorrhage and sepsis. Halsted's admirable "Review and Report Upon the Effect of Ligation of the Common Iliac Artery on the Circulation and Function of the Lower Extremities" was cited as a proof that it was possible to safely control hemorrhage incident to disarticulation by temporary or permanent interference with the common iliac current. Trendelenburg and Wyeth, who greatly improved the former method, were successful in a fair majority of instances by the use of transfexion pins to control the tourniquet. Deaver, Senn, and others applied the same principle of tourniquet control by various effective methods. McBurney, through the incision that bore his name, practised temporary manual compression of the common iliac with excellent results. Dr. Barney Brooks, in 1920, ligated the common iliac preliminary to hip joint disarticulation following previous amputation of the high in an emergency. Prevention and relief of shock were so dependent upon preoperative precaution, operative technique, and postoperative care, that

they were not discussed in detail. Sepsis was dismissed with the statement that it was a contributing cause of death so seldom during this age. When death from shock or hemorrhage followed so formidable a procedure it usually occurred before serious infection had time to make itself known, even though it were present to an alarming degree. Emphasis was placed upon the value of eliminating primary blood loss and shock following the original trauma before disarticulation was attempted and of re-establishing the resistance of the patient before proceeding with the operation. In cases requiring disarticulation at the hip, on account of malignancy in which the soft tissues were invaded, it was advisable to resect the involved muscle plane. This could not be safely or quickly done when a tourniquet was applied and was an indication for primary control of the blood current before operating, as a preliminary step. Reference was made to Walter Brashar, who, in 1806, performed the first disarticulation at the hip in this country, also to the admirable collection of statistics and report of 53 instances of hip joint amputation during the Civil War rehearsed in detail by Lieutenant-Colonel George A. Otis. The struggle to swing the formidable operation of hip joint exarticulation toward the safety column had met only with a measure of success one might rightfully expect from improved asepsis and surgical finesse. The death rate was still too high, and the control of hemorrhage and consequent diminution of shock by means that most assuredly did not increase the danger, was a logical aspiration. In cases in which the margin of safety was narrow and wherein loss of blood and augmented shock could not be tolerated, as well as in malignancy, preliminary ligation of the common iliac was advised. Such complete control of stump hemorrhage was thus obtained that the application of six to ten hemostats was sufficient to assure a dry field. Muscle planes could be gently approximated with negative tension without fear of oozing or of threatening the viability of the stump. He reported the case of a boy, 13 years of age, with a small cell sarcoma involving the right femur. The technic of the preliminary ligation and subsequent exarticulation was recited in detail. Both cases reported by Dr. Brooks and the author made an uninterrupted recovery. The technique of the ligation was remarkable only because of the ease with which the vessels were exposed and the operation concluded. Exarticulation at the hip joint was a hazardous procedure because of two factors. (1) The injury or disease making the step necessary had already seriously handicapped the patient. (2) Hemorrhage, shock, and sepsis in the presence of lowered vitality invited disaster. The logical solution, therefore, was (a) to refrain, unless forced by emergency, from further trauma until recuperation, compatible with safety, was complete; (b) replenish by blood transfusion the depleted circulation, and re-establish as far as possible the physiological activity of the sufferer; (c) control hemorrhage and therefore save time and shock by the five-minute procedure of preliminary ligation of the common iliac, and finally, treat operative shock before it developed by preventing all blood loss, nerve and tissue trauma, and prolonged anesthesia. It was in the belief that the steps suggested herein were directed toward safety, and were unfriendly to high mortality, that the case was reported.

Delayed Transplantation of Long Pedicled Flaps.—Dr. V. P. BLAIR of St. Louis said that the loss of a large cutaneous flap in a reparative operation was, at least, an embarrassment to the surgeon, and from the patient's viewpoint might approach perilously near to a tragedy. Good luck or shrewd judgment might carry one successfully through his earlier experiences when later he was confronted by a series of situations that called for explanations. The reason for this was that in the later work one had attempted bolder projects that could not be carried through on simple lines. Of the several precautionary measures to which one might resort in order to insure the vitality of a long pedicle flap, he would present the plan of delaying the transfer of the flap and, to give emphasis to his point, would present a series of incidents and one or two disasters that illustrated the advisability for these precautions. The cutaneous flaps made on young male adults and older men with healthy florid complexions had the most energetic circulation. Women, especially when pale or

flashy, had less energetic circulation in pedicle flaps, while in those made on children it was still more feeble. When death of a flap occurred, it was directly due to venous congestion dependent on inadequate return. In a pedicle flap whose base was at a lower level than the tip, blood return was assisted by gravity and stagnation was less likely to occur than when the tip was at a lower level than the base. In making a pedicle flap, about the vitality of which there was the least doubt, most of the uncertainty could be dispelled by dividing the operation into several steps—first, outlining the flap, raising it from its bed and immediately suturing it back into the same bed, after controlling all bleeding. The flap was allowed to remain there for a week or ten days before transferring it to its new position. At this later period either the circulation through the base had become vigorous or, if any part of the flap had died, the line of demarcation was already established. If the transfer was delayed more than two weeks, excessive shrinkage of the flap occurs and also the circulation through new vascular connections in the bed lessened the energy of the circulation through the base. In planning excessively long flaps they might first be made with a base attachment at each end and by repeatedly contracting the pedicle at one base adequate circulation might be established through the other base.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

PRÄKTIKUM DER KLINISCHEN CHEMISCHEN, MIKROSKOPISCHEN UND BAKTERIOLOGISCHEN UNTERSUCHUNGSMETHODEN. By Dr. M. KLOPFSTOCK and Dr. A. KOWARSKY. 518 pages with illustrations. Published by Urban & Schwarzenberg, Berlin and Vienna.

HYGIENE OF COMMUNICABLE DISEASES. By FRANCIS M. MUNSON, M.D. 793 pages with illustrations. Published by Paul B. Hoeber, New York.

ANAESTHETICS. By DUDLEY WILMOT BURTON, M.D. 548 pages with illustrations. Published by P. Blakiston's Son & Company, Philadelphia, Pa.

THE FORM AND FUNCTIONS OF THE CENTRAL NERVOUS SYSTEM. By FREDERICK TILNEY, M.D., and HENRY ALSPOP RILEY, M.D. 1020 pages with illustrations. Published by Paul B. Hoeber, New York.

INTRODUCTION TO GENERAL CHEMISTRY. By H. COPAUX. 195 pages with 30 illustrations. Published by P. Blakiston's Son & Company, Philadelphia.

THE 27TH ANNUAL REPORT OF THE MANAGERS AND OFFICERS OF THE CRAIG COLONY. 84 pages with illustrations.

THE HUMAN ATMOSPHERE. By WALTER J. KILNER, M.D. 300 pages with 64 illustrations. Published by E. P. Dutton & Co., New York.

THE ELEMENTS OF PRACTICAL PSYCHOANALYSIS. By PAUL BOUSFIELD, M.D. 276 pages. Published by E. P. Dutton & Co., New York.

A TEXT-BOOK OF MATERIA MEDICA. By HENRY G. GREENISH, M.D. 568 pages with 250 illustrations. Published by J. & A. Churchill, London.

THE DIFFICULTIES AND EMERGENCIES OF OBSTETRIC PRACTICE. By COMYNS BERKELEY, M.D. and VICTOR BONNEY, M.D. 809 pages with 309 illustrations. Published by P. Blakiston's Son & Co., Philadelphia.

HANDBUCH DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE, Bd. II, H. 6. By Dr. L. KATZ and Prof. Dr. F. BLUMENFELD. 365 pages with illustrations. Published by Curt Kabitzzsch, Leipzig.

JEWELS FROM THE ORIENT. By LUCY SEAMAN BAINBRIDGE. 125 pages with illustrations. Published by Fleming H. Revell Company, New York.

REPORT OF THE SURGEON GENERAL, U. S. ARMY, TO THE SECRETARY OF WAR, 1920. 755 pages. Government Printing Office, Washington.

THE BASIS OF PSYCHIATRY. By ALBERT C. BUCKLEY, M.D. 447 pages with 79 illustrations. Published by J. B. Lippincott Company, Philadelphia.

Therapeutic Hints.

Raised Blood-Pressure.—Sir Richard Douglas Powell, discussing the symptoms and treatment of raised blood-pressure, gives the following recommendations for anginal symptoms with severe dyspnea: Nitrate of amyl inhalations, and morphine and atropine subcutaneously, are the best remedies, the latter with due precautions. Oxygen inhalations are of great value in such cases. It will not infrequently be found that flatulent distention of the stomach starts the symptoms, and he is accustomed to recommend such patients to keep at hand a phial containing 5i of aromatic ammonia, 5i of tincture of cardamoms, ℥ ii of trinitrine solution, ℥ xv each of spirit of ether and of chloroform, and gr. xv of bicarbonate of soda in 1½ oz. of water, the phial to be marked in three divisions or "sips," one to be taken on threatening symptoms, the second in five minutes, and the rest if necessary, while the doctor is being sent for.—*The Practitioner*.

Scarlatina.—Goldstein advises against meddling some treatment and overtreatment in scarlatina. Among other details of treatment, in all septic cases and in cases threatened with uremia, he mentions the use, subcutaneously and even intravenously, of large amounts of sterile decinormal salt solution, as advised by Forchheimer, E. P. Carter, and others. The object is to dilute the poison circulating and as a mechanical aid to diuresis and the elimination of toxins. It is possible that in the severe toxic cases much might be gained by such measures if adopted early. In the vast majority of cases with slight sore throat, little fever, and only mild constitutional symptoms, all the treatment necessary will be isolation, rest in bed, diet and nursing, local care of the nasopharynx and skin, and the administration of an alkaline mixture as follows:

Sodii citratis.....5iii
Syrupi 5iv
Liq. potassii citratis
Liq. ammonii acetatis. . . .aa q. s. ad. 5iii

M. Sig.: One teaspoonful in sweetened water every two or three hours.

The Care of Snake-Bites.—G. C. Graves, who practised in the tropics for a number of years, suggests the following care of snake-bites: Immediately after a person has been bitten by a poisonous snake, the bitten limb should be surrounded by a tightly drawn bandage or handkerchief, as close to the bite as possible and between the trunk and the wound. The wound made by the fangs of the snake should then be freely incised with a knife and sucked. There is no danger in sucking the wound if there are no cracks or sores in the mouth or on the tongue. Do not cauterize the wounds. Do not administer alcohol in any form, or ammonia internally. The bitten person should now be removed to the nearest hospital and given antivenomous serum. This serum is a scientifically proved remedy and to be effectual must be used early, say within the first few hours after being bitten. It is the endeavor to keep a supply of this specific serum in each hospital so that all bitten persons may receive proper treatment.—*Indianapolis Medical Journal*.

THE RELATION OF THE MEDICAL PROFESSION TO THE COMMUNITY.*

By GEORGE GRAY WARD, JR., M.D., F.A.C.S.,
NEW YORK.

It is with a deep sense of appreciation of the honor you have conferred upon me by electing me your President that I arise to make my inaugural address to you in accordance with the mandate of our By-Laws.

The honor of being chosen to preside over an organization of nearly 3000 members representing the largest local medical society on this continent is a great compliment for which you have my heartfelt thanks, and I also appreciate in no small measure that you have not only conferred upon me a great honor, but a greater responsibility, which I approach with trepidation as I fully realize my deficiencies; however, the responsibility shall be met squarely with a zealous, honest effort to perform the duties of the office for the best interests of all to the extent of my ability.

The Medical Society of the County of New York, with its history of 127 years of service to the community, has a great heritage of which it may well be proud, and which should serve as a stimulus to meet the duties of the hour, which at no time throughout its long existence have been more urgent and serious than at the present day.

It is perhaps well for us to occasionally refresh our memories as to our duties by recalling the objects of this Society as written in our Constitution. They are "to aid in regulating the practice of medicine and surgery in the County of New York, and to aid in securing the enforcement of the laws relating thereto, to contribute to the diffusion of true science, particularly the knowledge of the healing art, and to assist in the preservation of the public health." Of the four objects thus outlined, three are related to legislative and legal matters and sanitation, and one to the scientific education of the profession.

It is thus apparent that this Society has important functions other than the scientific, and in that way differs from the usual medical organization. It is the one society in the community that is in close relation to the public through its activities in aiding State and county officials in regulating the practice of medicine and in enforcing the laws pertaining to it, and in education on matters of public health.

*Inaugural address of the President of the Medical Society of the County of New York, delivered January 24, 1921.

It is evident then that the relation of this Society to the community is of paramount importance. We must appreciate that this community, which we commonly speak of as the "public," has a different angle of view on medical subjects than our own. As Oliver Wendell Holmes says in his advice to the young practitioner: "This same community is very intelligent with respect to a great many subjects, but with regard to medicine it is hopelessly ignorant and never finds it out." But we must follow Holmes' advice and "take the community just as it is, and make the best of it." We can make the best of it, in my opinion, by instituting educational measures, and while it is a long road to travel, the results are commensurate with the efforts expended. You cannot force the community by legislation to exercise sound common sense in medical matters any more than you can force a horse to drink when you lead him to water.

During the 127 years that the Medical Society of the County of New York has been in existence, the practice of medicine has made marvelous progress. In that time the healing art has emerged from the Dark Ages of mysticism, superstition and empiricism to the broad daylight of scientifically demonstrable truths. Concomitant with the progress in scientific medicine there have occurred equally startling changes in the economics affecting the practitioners of medicine. Even to the casual observer there is a trend of events that, like the handwriting on the wall, points a warning that socialization of the profession and State medicine are at our very threshold. We are confronted not only with a threatened socialization, but with a tendency to paternalism which I believe is detrimental to the independence of scientific thought and action, that is undemocratic and therefore un-American. It behooves the profession then to act in unity through its organizations such as this one, to combat the various agencies which through misguided zeal or for personal aggrandizement are attempting to destroy all that has been gained by the profession of medicine in the centuries of progress toward the highest ideals. I believe that this can be best accomplished by united, persistent, and aggressive efforts to educate the public as to the real status of scientific medicine. We can then more efficiently fight such unsound doctrines as compulsory health insurance, health centers, and other paternalistic measures with which the community is threatened. I wish to record my hearty indorsement of the position of my predecessor, Dr. Chetwood, on compulsory health insurance. I believe with him that it is a pernicious and unsound measure in any form that it has been presented for legislative action up to the present time, and that it is wrong fundamentally

because it separates people into classes, which is contrary to democratic principles.

Let us outline the duties of our Society that we may more clearly see the road we have to travel in order to efficiently fulfil our functions. The Society has to perform its duty to the physician and its duty to the public.

Its duty to the physician may be subdivided into educational and legal relations. The educational relation is provided for in the scientific program which is arranged for each monthly meeting, and which should be of such character as to bring before the members authoritative data on the most advanced knowledge of medicine and should as far as possible cover all fields in such practical form as to be of most benefit to the general practitioner, and consequently to the general public. The legal duty of the Society to the physician is to safeguard his rights by keeping a careful watch on all pending legislation that may affect the profession or concern the public health, and to use its influence to see that the laws relating to the practice of medicine are properly enforced, and that a high standard of professional requirements shall be maintained. The Society should protect its members to the extent of its ability whenever they may be threatened with imposition or fraud.

The duty of the Society to the public is also both educational and legal. The public should be educated as to the economic value of medicine as a whole and to the status of scientific medicine by suitable lectures and propaganda on matters of public health. The broad problems relating to sanitation, tuberculosis, cancer education, pre- and post-natal care, the water supply, the safeguarding of milk, functional re-education, venereal propaganda, reformatories, the care of the insane, etc., are of equal importance in the education of the laity and of the physician. In spite of the fact that we are always suspected by the laity of having ulterior motives, it is necessary that the profession themselves shall be the leaders in medical economics and in making constructive efforts to safeguard the public health, or else the people at large through their elected representatives will attempt to regulate and direct legislation on such matters of which they are not competent to judge without the guidance of the medical profession. Constructive and not destructive policies should be our aim.

The most serious menace, in my opinion, to the public welfare is the continual pounding at the door of the rights and privileges of legalized medicine by those who seek these privileges without proper education. I believe that the state regulation of the practice of medicine should have uniform requirements of knowledge from all who would practise the healing art under whatever flag they wish to sail. There must be no avenue of entrance to the right to safeguard human lives except that of education. This attempt to break the barriers will be an ever present menace, therefore eternal vigilance must be the price of safety.

The educational measures that are needed by the public are varied. I believe that the most important of these is concerning the true status of scientific medicine, and that this education should begin in the schools. Our public school teachers are as a rule utterly ignorant of the simplest laws of

animal life, and we could make no better beginning than to provide a course of lectures on the broad principles of biology, physiology, and sanitation for our public school teachers. Here is work for our Public Health Education Committee.

A proper appreciation by the public of its responsibility and duty to the hospitals of the community is an urgent matter that cannot long be ignored unless the high standards which we are proud to believe have been maintained in our institutions must cease, or retrogress to an inadequate care of the sick.

They should be taught that hospitals are not business ventures but charitable organizations, and as such must depend on the public to *regularly* do its share toward the maintenance of institutions by which it is directly benefited. No one has felt the present high cost of commodities and service more than the hospitals, and it is the cause of much anxiety to trustees. The failure of the public to live up to its duty in this regard should concern this Society, and the need of educational propaganda is evident.

There is also a need for the education of the hospitals themselves. I mean especially the governors or trustees who are responsible for the proper performance of the functions of the hospital. Hospital trustees stand in the same relation to a hospital as trustees do to a trust fund, and they therefore should see that they get efficient results for the money they expend. They can only do this when they insist upon as careful an audit of their medical and surgical results as they do of their finances.

I have spoken much concerning the duty of this Society to the profession; what about the duty of the members to the Society? It is the duty of each member to see that those physicians in the county who are eligible, but who are not members, should lend their aid to form a united profession by joining the Society, especially at this time when state medicine, paternalism, bolshevism, and chiropractors, osteopaths, and their like are so rampant. Approximately 40 per cent. of the practitioners of medicine in this county, presumably eligible, are not members of the Society. No physician can afford not to be a member of his county society. Membership implies the hall-mark of good standing in the medical profession of the community.

We reached a milestone in the history of the Society this past year when we adopted a new constitution and by-laws. We are to be congratulated on this important step, which will facilitate the work of the Society and maintain its dignity and that of the profession, while at the same time it allows a proper and free avenue for any member to present or bring forward matters for the interests of all, as is fitting in a democratic organization.

The principal changes are:

First—The Comitia Minora has been made more democratic by the addition of four new members elected by the Society, namely, the Chairmen of the Committees on Civic Policy, Membership and Legislation, and the Assistant Treasurer.

Second—The creation of a Committee on Civic Policy whose function is to study those questions which determine the relation of the profession to

the commonwealth, and to advise the Comitia Minora and the Society on such matters, so that we may have carefully weighed and thoroughly digested opinions on which to base our actions.

Third—Citizenship or declared intention of citizenship is necessary for membership.

Fourth—That the routine procedure for stated meetings requires that motions which affect the general policy of the Society shall be presented in writing, and shall be referred to the Comitia Minora for consideration and advice, for the reason that the dignity of the Society and of the profession necessitates that precipitate action on superficially considered motions should be avoided, and that the meetings of the Society should be conducted with proper decorum.

I wish here to deprecate the practice of so-called "heckling" that has sometimes occurred, as it is usually indulged in for no real purpose other than the self exploitation of the "heckler," and cannot but obstruct business and reflect discredit on the Society as a whole.

Our thanks are due to the special committee who have labored so efficiently for the perfection of the new constitution and by-laws for the good of the Society.

May I say a word as to the need of always keeping before us the danger of contaminating our profession with commercialism? It is incompatible with the high ideals which we love to consider as an indispensable part of it. Utilizing the helpless ignorance and fears of patients to extract money from them is rank dishonesty and I am afraid is far too frequent a practice.

I also wish to call attention to an evil that I fear still exists in our midst. I mean that practice which is commonly known as "fee splitting." The work of the American College of Surgeons in combating this pernicious custom is so well known to you that it is unnecessary for me to say more than that it is the duty of this Society to use its every effort and influence to stamp it out, for the honor and dignity of our profession. I sincerely hope that the Society will go on record as opposed to this practice and will make such regulations as will not permit any member to remain in the Society who is guilty of the same.

In conclusion, let me remind you that the prestige of the Society depends upon the integrity, ability, and loyalty of the individuals who compose it, and if we wish to maintain it and also uphold the dignity of the profession in order that it shall not fall from the proud position it has occupied since the time of Hippocrates, as a result of the humanity, charity, and ever readiness for unselfish service for the public weal which has come to be associated with the name "physician," it is essential that we must keep before us as our duty the advancement of scientific truths, the abhorrence of the taint of commercialism, and strenuously fight for high ideals of conduct, and the honor and personal integrity of our members, remembering, as Browning says:

"The common problem, yours, mine, everyone's,
Is—not to fancy what were fair in life
Provided it *could* be—but, finding first
What *may* be, then find how to make it fair
Up to our means—"

48 EAST FIFTY-SECOND STREET.

DIAPHRAGMATIC HERNIA.

BY JOSEPH HAJEK, M.D.,

NEW YORK.

ASSISTANT ATTENDING PHYSICIAN, KNICKERBOCKER HOSPITAL.

SINCE the advent of the x-ray and fluoroscope, the diagnosis of diaphragmatic hernia is an established fact, and many cases are reported in recent literature. The subject of this paper is a patient who was admitted to the service of Dr. F. P. Solley, at the Knickerbocker Hospital, through whose courtesy I am enabled to make this report, in which the diagnosis was made clinically, and confirmed by autopsy.

REPORT OF CASE.—P. D., male, 46 years old, blacksmith by trade, walked into the hospital November 3, 1920, complaining of severe pain in his left chest, cough, dyspnea, and great weakness. The pain was situated over the precordium, entire left lateral and posterior chest, and had come on suddenly about twenty-four hours prior to admission. It was increased by deep respiration, and relieved by shallow breathing. The pain was constant, sharp, and accompanied by non-productive coughing; dyspnea and great weakness came on soon after the pain, causing much distress to the patient. Family history was negative. Patient, in his past life, had had all the diseases of childhood, a chronic cough for the past seven years, and shortness of breath accompanied by weakness for two years prior to admission. He had imbibed heavily all through his life. His appetite had always been good, bowels periodically constipated.

Physical Examination.—General: The patient presented good muscular and bony development with fair nutrition, but appeared acutely ill, his face wearing an anxious look, covered with perspiration, showing cyanosis around the lips and ears. There was marked dyspnea.

Head and neck: The eye reactions were normal; tongue dry and tremulous; teeth poor; otherwise no abnormalities.

Chest: The thorax showed a marked depression of the lower third of the sternum, the left side appearing to be enlarged, but presenting a diminished excursion. Apex beat not seen. Litten's absent on both sides. Fremitus greatly diminished on left side. Apex impulse not felt. On percussion, the left chest was tympanitic throughout except in its upper third. Respiratory sounds and spoken voice were greatly diminished. Succussion sign, to which the patient himself referred, was present, but was not of the pure metallic quality that one finds in hydropneumothorax. It was rather a lawless splashing, such as commonly occurs after drinking large quantities of fluids. No gurgling sounds were heard. The right chest showed an occasional rale at its base. The heart could not be definitely percussed; sounds were rapid and irregular, of poor muscular quality, distant, and best heard in the median line. No murmurs were audible.

Abdomen: Below the level of the costal margin presented tenderness and rigidity in its upper median portion. The liver was 8 cm. below the rib line; spleen not felt.

Extremities and reflexes: Normal. No lymphatic enlargement noted.

The diagnosis of strangulated diaphragmatic hernia was made.

Course of the illness: On admission the temperature registered 99°, pulse 116, respiration 26. The pulse was regular, but extremely weak and thready. Respiration very difficult. About four hours after admission the patient vomited brownish fluid and continued thus at frequent intervals until he died, twenty-four hours after admission. Temperature continued normal, pulse and respiration gradually increasing toward the end. Dyspnea and vomiting were very distressing. X-ray examination showed a uniform shadow through the entire left chest, with heart slightly dislocated toward the right.

Necropsy: Male subject, showing a deformity of the

sternum, characterized by a marked depression in its lower third. Upon opening the thoracic cavity the left lung was found to be compressed, occupying the apical cavity only. There was generalized fibrosis; no crepitation, indicating little or no function. Apex was adherent. The remaining portion of the chest cavity was occupied by the stomach, markedly distended, the splenic flexure of the colon, about two inches of the transverse, and two inches of the descending colon, covered with a portion of the omentum, as shown by the two accompanying diagrams.

FIG. 1.—This shows the heart in the median line, the stomach occupying the left chest cavity and remnant of the left lung.

FIG. 2.—Shows splenic flexure with a portion of transverse and descending colon situated behind the stomach, as shown in Fig. 1.

The stomach was greatly distended, filled with gas and about 300 c.c. of a dark brown fluid. It was folded upon itself in such a way that the esophageal opening and pyloric ring lay in the diaphragmatic opening, the pylorus showing signs of strangulation. The splenic flexure, with about two inches of the transverse and descending colon, were situated posteriorly. The left dome was poor in musculature and very thin. In the left lumbar costal area was a smooth-edged opening, lined with a tendon-like structure, which blended into the surrounding tissues and admitted five fingers freely. The hernia was in a sac formed by peritoneum and pleura. The liver was found to be enlarged, smooth, firm, and upon section showed extensive fibrosis. Gall-

bladder and ducts were normal. The heart was found exactly in the median line, was not enlarged, and without gross pathological changes. The other viscera were apparently normal.

Most writers divide diaphragmatic hernia into the following types: (1) True congenital; (2) False congenital; (3) True acquired; (4) False acquired; (5) Diaphragmatic eventration.

The true type has a distinct sac, consisting of either peritoneum or pleura, or both. The false hernia of the diaphragm, is devoid of sac. Etiologically, congenital hernias of the diaphragm, whether true or false, are due to imperfect development of the diaphragm; just what causes may be at work to prevent the closure of the dome, is not as yet definitely established. The true acquired types herniate along the course of one of the natural openings in the diaphragm, the esophageal, aortic, or that of the vena cava; occasionally they pass through the space of Larrey or the foramen of Bochdalek. In rare cases, this type of hernia may follow the absorption of a diaphragmatic gumma.¹ False acquired diaphragmatic hernia is usually due to stab wounds, crushing blows against the abdomen or thorax, and other trauma. Diaphragmatic eventration is simply due to thinning out of a portion of the dome of the diaphragm, which gradually elongates, forming a pouch which receives the viscera.

Location: By far the greatest number are located on the left side. Lacher² collected 276 cases, and found 225, or 81.5 per cent. on the left, and 42, or 15 per cent. on the right side. This ratio seems to hold good for both the congenital and the acquired types. The liver, in combination with the diaphragm, is the protecting factor on the right side, the right dome being anatomically much stronger than the left. The openings on the left side offer themselves as a natural way for a hernia, facilitated by the negative pressure in the thorax, and the esophageal opening is the one most frequently involved. Vogel³ states that the openings of vena cava and the aorta never have been the seat of a hernia. This is probably due to the fact that the former is protected by the liver, and the latter by the thick crura diaphragmatica and its situation posteriorly. According to Lacher,² the opening is more apt to be in the muscular than in the tendinous part of the diaphragm. The size of the opening varies, from a small aperture, to a complete absence of diaphragm, as in a case reported by Spessa.

Contents: The organs most frequently involved are the stomach, colon, omentum, small intestine, and spleen, in the order named.

As regards the sex, the acquired type is more frequent in males, while the congenital occurs with equal frequency in both sexes.

As to the age, the greatest number of hernias of the diaphragm occur during the first year of life, all these being congenital and frequently accompanied by other anatomical malformations.

Symptoms: These will often depend upon the length of time during which the hernia has formed, and the organs present in the dislocation. There may be none at all, or else the symptoms may be very indefinite, the patient suffering from mild attacks of indigestion, vague pains in the thorax for a long period, either until he dies from some inter-

current disease, or until the hernia strangulates. Dyspnea, as in our case, may be a prominent symptom; there may be attacks of coughing, with pain in the chest over the precordium, accompanied by dizziness and weakness. Hemoptysis may occur. Abdominal pain, singultus, or difficulty in swallowing, accompanied by vomiting, may also occur during distention. Constipation alternating with diarrhea is a frequent symptom. Alarming symptoms develop with great distention of the viscera, or strangulation, which, according to Vogel,¹ takes place in about 15 per cent. of cases.

Physical Signs: These will depend upon the size of the hernia. None whatever may be found. The patient may show some deformity, as in this case. The affected side may present diminished excursion, Litten's phenomena may be absent and apex impulse seen dislocated to the right. Fremitus is diminished or absent. On percussion, tympany is elicited, breath and voice sounds may be diminished, or entirely absent. There may be succussion, or rough gurgling or splashing sounds in the thorax. Heart dislocated. The abdominal signs may be those of tenderness or rigidity, in varying degree.

Differential Diagnosis: Chest conditions, such as pneumothorax, hydro- or pyo-pneumothorax, sub-diaphragmatic abscess, must be excluded. This usually is not difficult, if an x-ray examination can be made.

Prognosis: This should be very guarded, in view of the ever impending danger of strangulation; it depends largely upon the size of the opening, the mode of life, and the occupation of the patient.

Treatment: Aside from alleviation of the pain, surgery alone can avail. Thoractomy will be the operative procedure chosen, whenever the true condition is recognized. The hernia is reduced, and the diaphragmatic opening sutured, or if this is not possible the omentum may be sutured to the margin of the opening. In cases where an abdominal diagnosis only has been made, laparotomy will be the operation employed, and if the hernia cannot be reduced from below the operative procedure should be extended to an attempt to reduce it from above, by means of a thoractomy.

THE HISTORY OF THE DISCOVERY OF DUODENAL INTUBATION.

By JOHN C. HEMMETER, M.D.

BALTIMORE, MD.

PROFESSOR IN THE UNIVERSITY OF MARYLAND.

WHEN I first experimented with duodenal intubation twenty-five years ago (*Johns Hopkins Medical Bulletin*, April, 1895; *Archiv für Verdauungs-krankheiten*, 1896) I used the method for physiologic study of the bile and pancreatic juice. Some later workers on duodenal intubation, whose first publications did not appear until fourteen years after my original paper, would like to make it appear that I did not succeed in obtaining duodenal con-

tents, or that the pancreatic juice which was obtained was drawn, not from the duodenum, but from the stomach. Any unprejudiced worker who reads a description of my method can see that the method requires the emptying out of the stomach and distending it with a rubber balloon, which had a guide at the lesser curvature, through which the duodenal tube glided. It was impossible to get duodenal contents from the stomach under such conditions. Every gastroenterologist who has worked at all seriously and consecutively with the passing of stomach tubes, knows that it is an exceedingly rare thing to obtain pancreatic juice or bile from the stomach of a normal man or even of the patient. In paying attention to the frequency of this occurrence, I find it occurs about once in a hundred and sixty patients, and then there is, as a rule, some anatomical reason for it. I first worked with normal men.

In the mind of anyone who is not prejudiced, this could not be a criticism of my first method, which, as I have distinctly stated, was only one for experimental purposes. F. Kuhn, who had devised a method of his own for entering the duodenum, visited me in Baltimore, in 1899. His method consisted of the use of a very flexible, thin steel spiral tube, which was pushed through a thin stomach tube. He had become very dexterous with this instrument (see F. Kuhn, *Archiv für Verdauungs-krankheiten*, 1898), but advised me to try a long thin rubber catheter containing no metal spiral tube within it.*

Neither Kuhn nor I published anything about the use of long, soft rubber catheters in entering the duodenum, and which depended on the normal peristalsis of the stomach for entering the duodenum rather than upon some mechanical artifice or the *vis a tergo* of the manipulator.

I am under the impression that Kuhn published something about it in Germany, and believe I owe it to his brilliant work to make this statement in acknowledgment of his many years of experimentation on duodenal intubation. Owing to the vicissitudes of the war, I have not been able to come in contact with Kuhn to ascertain the journal and the date of his publication of this work.

In the *Archiv für Verdauungs-krankheiten*, Vol. XVII, 1911, page 482, I outlined the history of this promising method up to that date. This article contains some criticisms I made of Einhorn's statement that before the publication of his article in the *Internationale Beitr. zur Physiol. u. Pathol. d. Ernährungs Störungen*, Vol. 2, 1911, the only method of obtaining duodenal fluid consisted in the production of fistulas.

I consider that his brief mention of Kuhn's work and my own in Vol. XV of *Archiv für Verdauungs-krankheiten*, are inadequate and inaccurate. He says that we had only "attempted" this duodenal intubation. He should have added that we were successful. My efforts and those of Kuhn to perfect this method extended over a period of several years—as may be seen from the date of my first report, April, 1895, in *Johns Hopkins Hospital Bulletin* and in my text book on "Diseases of the

*Fenton B. Turck had succeeded by simple rubber tubes in entering the duodenum; the method seemed promising.

Stomach," 1897. That these efforts actually were crowned with success does not exclude the possibility that subsequently another man could discover a more practical method.

It was the express purpose of my study on duodenal intubation, which was published in *Archiv für Verdauungs-krankheiten*, in 1896, that it should serve as an incentive to other workers. For in the series of subsequent workers in this special technical field Einhorn is not the second in historic order of those clinicians who have occupied themselves with experimentation and perfection of the technique of duodenal intubation, but, as we shall soon become convinced by the chronological sequence of the dates of publications on this subject, he is but the fourth.

It is not ingenuous to throw doubt on the work of a fellow investigator by stating, twelve years after the date of publication of his original work, that Einhorn did not know whether he (J. C. Hemmeter) obtained duodenal juice or not.

Einhorn writes as if I made only one single experiment, whereas the articles in the *Johns Hopkins Hospital Bulletin*, April, 1895, and also in my text book on "Diseases of the Stomach," 1896, prove that the original method was the result of several years of experimentation.

In a little book, entitled "The Duodenal Tube and Its Possibilities," published in June, 1920, Einhorn goes over the history of duodenal intubation as he views it, but he still cannot reconcile himself to the fact that I obtained the duodenal contents by my original method in 1895, fourteen years before Einhorn published anything about his methods. He gives as references of my work an article in *Archiv für Verdauungs-krankheiten*, 1897, vol. 2, page 85.

It can be readily proved that I publish nothing whatever in those archives in 1897. The article in question was published in 1896, vol. 2, page 85, of the *Archiv für Verdauungs-krankheiten*, but even this date is not the first of my publication of duodenal intubation. The very first publication of this subject by me will be found in the *Johns Hopkins Hospital Bulletin* for April, 1895. Maurice H. Gross and I. W. Held, in a book entitled "The Therapeutics of the Gastrointestinal Tract," translated from the work of Carl Wegele, give the correct historic sequence of these publications, on page 255 of their work.

The article in the *Johns Hopkins Bulletin* represented a report of a demonstration before the Johns Hopkins Medical Society, and it is the first public announcement of any idea to reach the duodenum in a systematic manner. I expressed the hope at that time that later experiments would simplify and perfect the method.

Einhorn states (last column, page 19, of his little book on the duodenal tube) that one cannot obtain a mold of any particular stomach so that the rubber bag will tally exactly with the shape of the stomach and, therefore, he says it is impossible to say whether the opening of the groove in the bag, which is to serve for a guide to the duodenal tube along the lesser curvature, is readily opposite the pylorus. To this I would reply that our first experiments were on animals and the second series on normal human beings, and that the capacity and size of the stomach was ascertained before the stomach-shaped rubber bag was introduced; in

other words, a large stomach required a large intra-gastric bag and a small stomach a small bag.

In the description of Kuhn's method, Einhorn is equally severe as of my own method, forgetting that Kuhn and myself were pioneer workers, and that we expressly stated that we hoped our methods would later be improved upon.

Einhorn's publications of 1908 in the *New York Medical Journal*, and 1909 in the *MEDICAL RECORD*, do not concern the reaching of the duodenum with a rubber duodenal tube, but they are experiments to estimate the permeability of the pylorus. This was done by threading beads and little bags containing dimethylamidoazobenzol agar to indicate the change of reaction when the thread holding the beads passes through the stomach or into the duodenum. The beads are inclosed in a gelatine capsule and given to the patient; six hours later they are withdrawn and inspected, at a time when there is presumably free hydrochloric acid in the stomach. The string may have two such capsules, ten inches apart. If after they are withdrawn both beads are in the stomach, the agar will in both cases be red. If one bead is in the stomach and the other in the duodenum, the stomach bead will be red and the duodenal bead will be yellow. Einhorn then went on to devise the duodenal bucket. All of these are ingenious contrivances for which Einhorn is famous, but his duodenal tube was not published until 1910.

It is evident from the publication of Maurice Gross that in May, 1909, he had used a duodenal tube in the outdoor department of the Roosevelt Hospital in New York, and in September, 1909, that he succeeded in obtaining duodenal contents. The testimony of Drs. W. G. Lyle and Eleanor Parry, and M. G. MacNevin, bear him out in this claim, but on Jan. 8, 1910, Maurice Gross published his first article on that subject in the *New York Medical Journal*. At that time Einhorn had not yet published his article on the duodenal tube of his design.

Gross sought to facilitate the passage of the tube through the pylorus by gravity, for he placed the patient on the right side and weighted the end of the tube with a little ball, which was the first design of this kind.

M. E. Rehfuss had this same idea in mind (M. E. Rehfuss: A Modified Gastro-Duodenal Tube, *New York Medical Journal*, Aug. 22, 1914) when he made the capsule end of his duodenal tube heavier. Einhorn criticises this method also, claiming that the heavy end of tubes, like those of Rehfuss, Maurice H. Gross and B. Vincent Lyon, exert undue pressure on the gastric or duodenal mucosa. Also that the big openings allow coarser food particles to enter the tubes which are apt to clog it. However, in these experiments no such coarse food particles are used, at least not as a rule. In fact, we must be prepared to look forward to various modifications and improvements of the duodenal tube; we will eventually reach a tube which will be so perfect that the devices of all the clinicians I have mentioned will appear simply as intermediate stages in the development of this technique. More recently Palefsky, J. Buckstein, and Jutte have already added valuable improvements to this technique.

Scientific progress can be favored only if it meets with a warm, sincere appreciation and with an ingenious sympathetic and just regard for the work

of those who have preceded us. To meet the work of all previous workers with one criticism or another is an evidence of a spirit of contentiousness which is a hindrance to progress. Above all things a clinician must be sincere enough not to criticise a method which he has not tried himself, nor even personally witnessed as carried out by the originator. That there are imperfections in the pioneer methods of clinical technique is evident in all fields of medicine and surgery where clinical pathfinders have first blazed a way for a new method of diagnosis.

There are curious contradictions in Einhorn's reply (in *Archiv für Verdauungs-krankheiten*, 1911). For instance, on page 362 (tenth line) he asserts that "Hemmeter and Kuhn obtained fluid by direct tubing from the duodenum." On the following page his opinion has already changed, for he says (on page 363, third line) that "Hemmeter has not yet proved that he was really in the duodenum with his instrument."

Einhorn supposes that the fluid was extracted by suction of the tube from the stomach, a supposition which betrays an ignorance of the method, quite apart from the fact that the duodenal contents flowing back into the stomach never show such pronounced diastatic, proteolytic and lipolytic powers as my figures show in that article.

I have reported in the same pages that my method could not be carried out at all if the stomach was not previously completely filled with the intra-gastric balloon. This has been the sole object of the balloon method to fill the stomach completely so that the canal running through the lesser curvature could not lead elsewhere than into the duodenum. The stomach must first be washed out before it is filled out with the balloon. It is impossible that any fluid could be drawn up from the stomach after his procedure. (See Hemmeter textbook, "Diseases of the Stomach," third edition, pages 56 and 57.)

In the *Archiv für Verdauungs-krankheiten*, No. 1, page 363, Einhorn says that pure duodenal fluid without admixture of gastric juice can be obtained by his method. If he means the fluid which may happen to have collected in the duodenum at the time of the test, I will not dispute his contention. But that is not what I mean. Pure pancreatic juice is the most powerful factor, and that is not obtained "over night"; it is secreted only after previous physiological stimulation of the normal chemical processes in the stomach and controlled by the vagus.

The chemico-dynamic and nervous influences which dominate the gastric, duodenal, pancreatic and liver secretions are in every way so wonderfully delicate and reciprocally adapted that even the slightest deviation from the normal of any of the chemical, dynamic or nervous phenomena is accompanied by irregularities. The knowledge of these phenomena is so far advanced that today it is doubtful whether one ever finds quite normal conditions in the analysis of the stomach test meal. Absolutely pure pancreatic juice is obtainable only by inserting cannulas into the pancreatic duct (J. P. Pawlow). All duodenal juice must contain a mixture of bile, succus entericus and pancreatic juice and sometimes gastric juice.

Einhorn is not the only one who has published

a method of duodenal intubation in which the peristaltic stomach itself aids the instrument. M. Gross of New York wrote me that he invented a duodenal tube based on nearly the same idea before Einhorn. His report of the tube appeared in *Journal of the American Medical Association* (1910, vol. 23, p. 4).

F. Kuhn described fourteen years ago and carried out measurements and dilatations of the pylorus and I have never asserted that the method of Einhorn, Gross, Kuhn or of anyone else has anything in common with my first method.

It is a source of pleasure to me that four other workers have pursued the study of the duodenum, and no one has criticised my method so severely as I did myself in the *Archiv für Verdauungs-krankheiten* in 1896, where I explicitly stated that mine was only a tentative method, intended chiefly to incite others to take up this study. The very fact that I took up with Kuhn's method later on, as Einhorn correctly narrates, shows that I hoped it would be an improvement upon my own. Kuhn visited and spent some time at my clinic at the University of Maryland, and we both observed that very small rubber catheters, when introduced alone, and not containing the Kuhn metal spiral inside of them, would slip through the pylorus occasionally, and as he desired to publish this method, an improvement on his own, I have not published it myself.

As illustrating the rapid advance which the discipline of duodenal intubation is making, I call attention to an article on "Intubation and Visualization of the Duodenum with the Duodenal Tube," by I. O. Palefski, in the *Journal of the A. M. A.* for Dec. 4, 1920 (vol. 75, p. 1547). Palefski here states and illustrates the various sizes, shapes and weights of the ends of five different duodenal tubes designed by five different clinicians, the weight of the ends varying from 33 to 105 grains. He omits two other modifications of the tube and Buckstein's interesting study on "Delineation of the Intestines by Means of the Duodenal Tube," of this latter author's own design.

Einhorn has contributed so many valuable new conceptions to medicine, and his mind is so resourceful, his inventive power so marked for the designing of new mechanical contrivances that facilitate diagnosis and treatment, and he has met with so much appreciation by his fellow workers, that it is regrettable to find in his booklet on the duodenal tube nothing but criticisms for the inventions of his coworkers in the same field, and that these fault-findings are not based on a personal experience with these instruments, but simply from deductions formulated after a process of speculating about them.

The whole question of the history of the discovery of the duodenal tube might be left to a natural sequence of chronology, because the question now is, not, "who has invented this or that duodenal tube," but the most important question is, "In whose mind, and when, did the idea of intubating the duodenum, and therefore, the intestine, systematically, first originate?"

Spallanzani, who was born in 1729, nearly 200 years ago, was the first to make animals swallow metal tubes closed by a grating at each end, in order to allow the freer entrance of fluid, and he sometimes used hollow spheres made of two hemi-

spheres screwed together, the walls being freely perforated. These tubes or spheres he filled with meat, bread, or bone. He recovered them from birds and other animals by making them reject these contrivances through the mouth; but he also made animals swallow pieces of meat and the like, so attached to threads or wire, that he could, after a while, withdraw them from the stomach. (*Lectures on the History of Physiology by Sir M. Foster*, 1901, p. 213). This was the beginning of the use of silk strings for obtaining information concerning the stomach contents, bloodstains, etc.

A great deal more has still to be learned. The instruments or the duodenal tube of various designs should be worked out in clinical practice with a view to determining which is the most practical and which is the least harmful tube. The weights at the end of the duodenal tube which Palefski described have no other purpose than to accelerate and facilitate the passage through the pylorus.

I have found with almost all of these ends to duodenal tubes that the metal end itself may be sufficient to draw a certain amount of blood from the capillaries of the duodenum in individuals who gave a negative string test on two occasions before this duodenal tube was introduced. Inasmuch as a silk string can pass through the pylorus eventually, the weight of the end of the tube may quicken the process of intubation, but in certain conditions of nervous pyloric spasms, which may be induced by this very procedure, the metal end itself may be the cause of this small amount of blood. The question is, then, not "*which tube enters the duodenum most quickly?*" but "*which enters it most safely?*" At present I am using a tube which is constructed entirely of rubber. If it takes longer than the metal ended tube, I instruct the nurse to introduce it the evening before I want to make my duodenal observations. I use the tubes with metal tips also, but only in cases where I feel quite sure that all diagnostic methods directed toward exclusion of pyloric spasm and pyloric obstruction have been exhausted.

I wish to express a word of warning concerning the introduction of the intestinal tube too far down into the intestine and attempting to pull it back through the stomach. In one case, a condition of intestinal obstruction was superinduced in my experience, which gave every indication of a traumatic invagination. In all such cases where over 75 cm. of tube have been introduced, the tube should not be withdrawn through the mouth, but be permitted to pass out through the rectum. No matter how gently the withdrawal through the mouth is done, in a patient that is in a highly vagotonic condition, local intestinal spasms can be produced, and if the clinician pulls against these localized intestinal constrictions, one part of the ileum may be pulled up into a higher and wider part of the ileum. This is not a frequent occurrence, fortunately. I have observed it only once, but consider it a duty to report this occurrence.

Einhorn means to suggest that I gave a demonstration of the first method of duodenal intubation in 1895 before the Johns Hopkins Hospital Medical Society and also published the new method in the *Archiv für Verdauungs-krankheiten* in 1896, and in the various editions of my textbook on "Diseases of the

Stomach," and also in the two volume textbook on the "Diseases of the Intestines," and did not assure myself that the end of the duodenal tube was in the duodenum. He keeps on implying that the alkaline juice containing trypsin, amyllopsin and steapsin, which I withdrew, was not obtained from the duodenum, but from the stomach of the person under observation. My clinical studies were carried on for over one year in many normal subjects and demonstrated before my classes before I published a word about them. By the very nature of the method (lavage of stomach as a preliminary step, then complete filling out of the entire lumen of the stomach) any drawing of bile or pancreatic juice regurgitated into the stomach is impossible. Besides, my duodenal tube of 1896 was so constructed that it could not double up or reduplicate, hence, this first duodenal tube, if it moved onward at all, must unfaillingly move through the pylorus.

In June, 1896, an article from my clinic appeared in the *Boston Medical and Surgical Journal* (p. 609), entitled "Photography of the Human Stomach by the Roentgen Ray." These experiments were later on repeated and improved upon by Drs. Harry Adler and Robert Bay. (See "The Diagnosis of Ulcer of the Stomach and Duodenum by the Roentgen Ray," *Jour. A. M. A.*, Nov. 12, 1910; also, Adler and Ashbury, *New York Med. Jour.*, Oct. 7, 1911.) I cite these experiments to prove that in my clinic the first experiments aiming at radiography of the stomach were undertaken. (See "Priority of Employment of the Roentgen Ray in Studying the Physiology and Pathology of the Digestive Tract" *Journ. Am. Med. Assoc.*, Oct. 5, 1912, vol. 59, p. 1308; see also "Clinical Diagnosis of Internal Diseases," by Lewellys F. Barker, vol. ii, p. 307.)

We were therefore familiar with a technique for gastroenterologic radiography as far back as 1896, and we availed ourselves of this method to make sure that our primitive duodenal tube really was in the duodenum.

As to our own personal convictions, they are as follows: We obtained the same duodenal contents twenty-four years ago under various normal and pathological conditions as we do today with Lyons' or Rehfuß's tube. And we obtained them too often to permit of any doubt as to the source of derivation of the aspirated juice. This entire controversy is provoked by Einhorn alone, none of the other many workers with duodenal intubation having ever expressed any doubts as to my first experimental work.

The reason why Einhorn throws this doubt on my original clinical method is that he considers himself the first one to have successfully and systematically entered the duodenum by a tube.

It can be proved beyond the possibility of a doubt that not only I, but Franz Kuhn (*Archiv für Verdauungs-krankheiten*, Bd. III, p. 19, 1918) and Maurice Gross preceded him (it is true by methods of different design). (See "Zur Geschichte d. Duodenal-intubation," etc., *Archiv für Verdauungs-krankheiten*, Bd. XVII, p. 136), which represents one of my earlier defenses against Einhorn's claims that no one intubated the duodenum before he did.

That my original method was imperfect and was superseded by better ones constitutes no detracting from my historic priority. The original (Kuss-

naul) stomach tube has also been improved, yet no one desires to rob Kussmaul of the merits of his pioneer work.

739 UNIVERSITY PARKWAY.

SPEAKING OF SPECIALISTS.*

BY INEZ C. PHILBRICK, A.M., M.D.,

LINCOLN, NEB.

THE statement of my subject may warrant the inference that in its choice I had in mind to rival a recent humorous essay on the subject of operations, but such was not the case. None other than some medical Mark Twain could extract and utilize to the full the humorous possibilities in the excesses and absurdities of present-day specialism, and none other could portray them in more kindly fashion, as the inevitable reaction of our profession to the necessities of a competitive environment. If it be objected that my subject lacks definition, it was so intended—to be simply a point of departure, allowing wide excursions into a wide field. When one's ideas are exploration-bound, it is disturbing to run up against the hard-and-fast confines of a subject. In order that I may not be misunderstood, please consider my critical references to specialists in particular, as being directed toward clinical rather than special-sense or laboratory specialists.

Consideration of this subject brings first to mind the question—"Who is a specialist?" Its correct answer is of vital import to all of us. It may be that, unbeknown, some who have never presumed to the title are *very* specialists; and others, who have assumed it, are general—*very* general—practitioners. By what authority is one a specialist? Is it by natural gift—by education—by pursuit—by experience—by attraction of a special field—by greed for personal gain? Is specialism essentially an entity, or is it a state of mind? Is the word "specialist" often merely a catchword? The dictionary gives, as the conditions that determine specialism, "a limited field," which is naturally separable from the field of general medicine; one requiring of him who cultivates it a greater skill, a closer concentration, and different methods and mechanical aids than is and are demanded of the general practitioner.

In the light of the foregoing questions, and these conditions, and our own experience, it is evident that there are specialists and specialists—some genuine, more spurious; some needed, more superfluous.

Specialism has marked the course of biology as of human institutions, it being the necessary means of adaptation to an increasingly complex environment. Paleontological records visualize the procession of now-extinct species. Today we foresee the extinction of the domestic horse, its specialization for speed having reached practically its limit—a limit far short of insuring successful competition with that of the man-made automobile and aeroplane. Extinct civilizations have marked the passing ages, each having developed through the centuries of its existence an environment even more complex and a specializa-

tion finally incapable of further adaptation. To-day in industry, in business, in education, in all the phases of our complex existence (I will not call it life), we see the workings of specialization directed toward conquest of environment.

The modern factory affords a striking exhibition of its extreme development and irimical results. In the workman who is required to make ever daily, weekly, yearly, by mechanical device, the same small part of the to-be-finished product, creative ability and joy in work are stifled. The product thereby loses in quality, in individuality, in that illusive something that marked the product of the hand-worker of apprentice days. The purpose of this specialization is accomplished—to increase dexterity, speed and output, thereby lessening cost and increasing profit to the manufacturer in competition with other manufacturers in the field of trade; in other words, thereby is achieved adaptation to the environment of competitive trade. The minute specialization in every detail of the successful modern business is a thing of astonishment to the uninitiated. The skill, time, and money expended upon the one factor in success—advertising—is stupendous in amount and in results. In the hands of the successful advertiser the public is as wax.

In education, vocational education, which fits for trade, is displacing the humanities, which fit for living.

To-day our profession, on a competitive basis, faces the necessity of adaptation to an environment rapidly increasing in complexity. Three factors in such complexity are, first, its own overcrowded ranks, representing all kinds and degrees of preparation and fitness and their opposites; second, an increasingly exacting public, possessing superficial knowledge gained through press and from platform, suspicious (with reason) of our capabilities and good faith, impressed by the catchword "scientific," credulous in the presence of tests, formulae and apparatus; and third, a rapidly increasing number of mechanico-theraputists of various names, whose theory and practice, if unenlightened, are definite, and who do *do* something tangible for their patients. Naturally, in such an environment, specialists and specialties appear over night, and new tests, formulae, methods, and mechanical devices crowd upon us in bewildering confusion—many of them but the passes of the medical juggler to hypnotize his clientele. In medicine, far greater than in industry or business, are the inimical results of over-specialization and of mechanical methods, of loss of perspective, and of vital and consecutive interest in the whole man. Specialism, unco-ordinated, is portrayed in the story of the blind man and the elephant—all tail, all trunk, all flank, according to the part handled. So in medicine—all nasopharynx, all colon, all internal secretions, all focal infection, according to one's specialty.

The situation is profoundly disquieting and is explicable only to the medical sociologist, who links up medicine with other social institutions, and the present with the past. Clearly, present professional tendencies persisting, destruction of medical unity, utter disintegration, are inevitable.

Is there no lessen out of biology and history to

*Read before the Lancaster County Medical Society, Oct. 23, 1920.

point the way to organization of medicine upon an enduring basis? Through all time, the law of existence for plant and beast and man has been that of the jungle; survival of the fittest—the fittest to survive on the plane of force and material advantage—the plane of competition. Species, civilizations, institutions, have arisen, grown more and more complex, all in the end suffering extinction. The lesson to me seems clear. Specialization, conditioned upon competition, separates the individual from his group, entailing his own extinction and that of the group, weakened by the defection of its individual members. Specialization with co-operation binds the individual to his group and makes for the endurance of both. If medicine is to endure, it must be organized upon the basis of specialism, conditioned upon cooperation and simplification.

The private medical group—a strategical group, allowing of better defense of its members from the onslaughts of other members of the profession, and of more successful forays upon the public—does evidence at least unconscious recognition on the part of many physicians of the necessity of medical organization upon an at least partially co-operative basis. At present, however, competition between different groups being necessarily more acute than that between individual physicians, because better organized, and the better service to be had within the group offset by the greater expense of such service, it is doubtful if professional conditions in general are much improved thereby.

An epochal book received a few days ago while in the midst of preparation of this paper—Sir James Mackenzie's "The Future of Medicine," presents an argument (supported by facts out of his large experience) for simplification of medical education and practice, for fuller utilization of clinical observation in medical diagnosis and treatment, and for organization of the profession about the physician—the general practitioner, who alone can have consecutive observation of the patient through a term of years, and who alone can effectively serve in the first two of the four stages into which Mackenzie divides disease—the stages of predisposition, early disease (with no objective symptoms), late disease (with objective symptoms), and the final stage, in which alone the pathologist, through the autopsy, can profit.

Says Dr. Mackenzie: "I am convinced that the concept of specialism dominant today is a wrong one, and that, helpful as this specialism has been in many ways, instead of enlightening it tends to darken understanding in a cloud of detail." A just criticism when directed toward the spurious and excessive specialism of the day. Dr. Mackenzie does not in this book discuss the philosophical basis of specialism, as I have tried to do in this paper.

While outside the medical colleges there is growing recognition of the impossibility of the student covering, even perfunctorily, the entire range of subjects assigned to every would-be graduate in medicine, the makers of curricula do not seem to have sensed the necessity of reorganization of medical education upon the basis of necessary and sane specialism. In a recent article in the *Journal of the A. M. A.*, Frederick Peterson

of New York faithfully reproduces in parody the syllabus recently recommended for first-year students by the professor of clinical medicine at Johns Hopkins, as quoted in "The Future of Medicine," the syllabus covering by actual measurement four and one-fifth pages of 6 by 3 2/3 inches of nonpareil type. Such a recommendation from such a source is both ludicrous and tragical—ludicrous in its reflection of the un wisdom of the present-day makers of curricula, and tragical in its consequences to the student and the clientele he will later serve.

The first logical step in reorganization of medical education upon the basis of specialism with simplification, should be determination of the fitness of the prospective student to enter the profession of medicine; his general fitness to be determined by reports from parents or guardian and former teachers, covering his personal traits and aptitudes and progress in secondary school and college; his fitness for some particular field to be determined by psychological and actual performance tests. Obviously, the qualities fitting one for laboratory research are not the same as those demanded of him who must meet the emergencies confronting the surgeon. Most rigorous and discriminatory of all should be the tests applied to the would-be future clinicians, surgeons, and obstetricians, who should at least give evidence of possession of more than average intelligence, judgment, moral perception, altruistic spirit, and capacity for work. The student having settled upon the special field of his future labors, all training from the beginning should be directed toward his specific needs. Courses varying in content and time consumed in their pursuit, and simplified by elimination of all irrelevant facts, tests, methods and apparatus not of proven value, should be adapted to meet the needs of future workers in different fields. To require from future ophthalmologist and obstetrician the same general course is the height of absurdity.

In the field of applied medicine, the *sine qua non* in organization is the elimination of financial competition, the establishment of cooperation through the inclusive community group—the only practicable working basis of specialized practice. Financial competition once eliminated, simplification of environment in this field will come, first, from decrease in the number of specialists and general practitioners in any community to meet its real needs. Our profession, once released from the necessities of competitive practice, could easily furnish the necessary data for determination of this necessary quota. Every member of the profession knows that inevitably, under present conditions of practice, the large majority of tests and visits made and operations performed are superfluous. Simplification will come also by decrease in the number of cases requiring medical attention, through the effective operation of public health agencies and the cutting off of the supply of defectives through enlightened social legislation.

Financial competition being abolished, the specialist will naturally assume his proper place in the medical scheme—that of the consultant. As such, the general practitioner can profit by his

full abilities; the patient will be protected from the results of excessive enthusiasm in the pursuit of his specialty, and the specialist himself, relieved of the necessity of foraging for patients, will have time and energies free to devote to the minute requirements of his special field.

Further simplification must come through the elimination of spurious specialties, which are largely the outgrowth of financial competition. The question arises: "How wide may be the field of the legitimate specialist?" Among specialists I have known there have been those who, by advertisement, to pediatrics have added obstetrics; and in practice, to obstetrics have added clinical medicine; and to clinical medicine, bacteriology; and to bacteriology any remaining medical territory. Obviously, with such, specialism is camouflage.

Some years ago, when pediatrics was young, I wrote a paper for the Pawnee Medical Society in which I maintained the illegitimacy of its claim as a specialty. The argument is as valid now as then, and is further fortified by the advance of public-health medicine which, through general public health officers and medical school examiners, has annexed a large part of the pediatric field. The fields covered by pediatrics and general medicine are continually found to be more nearly coextensive, there being but a narrow margin about either in which the diseases of the other, if infrequent, are not unknown. The same general methods of examination and treatment apply in the one as in the other, the pediatricist having no greater need to modify and adapt than has the general practitioner. The only distinctive field that pediatrics can claim is that concerned with the developmental processes of infancy and their morbidity and pathology, and these do not constitute a sufficient *raison d'être*. On this basis, geriatrics has equal claim as a specialty. Regulation of infant feeding, which constitutes such a preponderant part of the labors and emoluments of the pediatricist, falls logically to the obstetrician or general practitioner, in consultation, if need be, with the specialist dietician. Any intelligent physician is capable of grasping the essentials of correct feeding, and, if accorded the opportunity of experimentation with a succession of formulæ through a period of weeks, is quite capable of meeting the demands of the most exacting infantile stomach—provided, of course, the infant survives the experimentation. However, under present conditions of practice, knowing that such opportunity will not be accorded the *mere* physician by a clientele hypnotized by the dazzle of specialism, it is the part of least resistance, discretion, and peace of mind for such an one early to relinquish the case to the pediatricist, who otherwise, at the insistence of the family, will appropriate the same. Unquestionably, withdrawal of infant feeding from the field of specialism would promptly result in its simplification and thereby redound to the interests of the infant. The conclusion of all this is that the differentiation of pediatrics from general medicine is an artificial division and not a natural cleavage, with the result of the pediatricist annexing the family practice rather than of medical progress being advanced.

Gynecology is another so-called specialty that has no claim to separate existence, its field being practically covered by obstetrics and surgery. In these it should be merged. Time forbids consideration of other spurious specialties.

The weaknesses of medicine have been not only those of commission, but those of omission as well. There has been lack of needed specialties, as there has been surfeit of useless and spurious ones. For example, we need specialist consultants in therapeutics—those having faith, as well as knowledge founded upon experience, in the use of drugs and many other remedial agencies. It is the universal experience that in counsel we receive aid in diagnosis, but seldom in treatment. In that field of applied medicine which, in the past, has claimed most of our time, study, and effort—the relief of the physical ills of mankind—the profession has failed most signally. Lack of standardization and positiveness of treatment, and bigoted rejection of many mechanical and psychic methods of treatment, have been responsible for the rise of many healing cults of various names, with loss to our profession of many patients; and to these patients, as we believe, of adequate service.

That the profession of law, devoted largely to the safeguarding of property, should be far better organized in the mutual interests of lawyer and client than the medical profession, devoted to the safeguarding of health and life, is organized in the mutual interests of physician and patient, is explicable only on the supposition (well founded) that people are neither credulous nor long-suffering when concerned with affairs of the pocketbook. In the modicum of voluntary organization that has obtained in the field of applied medicine, there has been provision for neither legislative nor judicial machinery. Councils on standardization and courts of appeal are as vitally needed in medicine as in law or government, and will naturally arise under the operation of cooperative medicine.

To summarize: Specialization is the necessary adaptation to a complex environment. Specialization conditioned upon competition dooms to extinction. Specialization conditioned upon cooperation insures endurance. In medicine, specialization and coordination must go hand in hand, and the physician, the general practitioner, is the logical coordinator. Specialists are, in the nature of things, consultants, and cannot in reason be competitors. Genuine specialism, conditioned upon cooperation and simplification of the medical environment in all its ramifications, will alone insure the endurance and advancement of medicine.

1023 H STREET.

Presumption of Verminosis.—On account of the great frequency and variety of intestinal parasites Labbé believes it rational to suspect their presence in nearly every case of gastrointestinal disorder until it can be definitely excluded. Ordinary dyspepsia, painful crises and false appendicitis, diarrhea with or without alternating constipation, pseudo-hepatic colic and other familiar affections should make us suspicious. If to local disturbances there is added emaciation the practitioner should think of worms as well as cancer. Chronic enterocolitis is the most common consequence of verminosis.—*Gazette des Hôpitaux*.

A CONCEPT OF X-RAY PATHOLOGY.

VII. CRANIOPATHIES.

By A. J. PACINI, M.D.,

WASHINGTON, D. C.

CHIEF OF LABORATORY AND X-RAY SECTION, HOSPITAL DIVISION,
U. S. PUBLIC HEALTH SERVICE.

(Concluded from page 316.)

X-Ray Horizontal.—Recalling how Camper compared the facial angle to the horizontal, and how this observer directed attention to the significance of a facial angle that assumes a horizontal position, it would seem fundamentally imperative that a judiciously chosen horizontal be selected as a basis for x-ray studies. Cranial skeletal embryology furnishes the clue. It is remembered how the facial bones and the skull base are derived from cartilage, and how the bones of the vault are membranous in development. The unyielding basal plane, therefore, acts as a resistant surface on which the superimposed brain lies. Any changes that may be induced by the cerebral pressure in its growth are reflected upon the membranous vault. If the base were smooth, the semifluid brain would exert its pressure equally on the membranous vault and a hemispherical cranium should in all cases be expected; but the base lines in three levels corresponding to the anterior cranial fossa, the middle cranial fossa and the posterior cranial fossa, each fossa curved and on a lower level and facing a different direction than its neighbor. Therefore, the growing cranial contents exerts its pressure on three parts of the membranous vault with greater intensity than the remaining membrane. These areas are, from afore backward, the frontal region, the supraoccipital and the infraoccipital.

The supraoccipital region is opposite the superior maxilla; in other words, opposite that portion of the cranial skeleton that is most reinforced. This enables the cranial contents to exert its greatest pressure in this direction, and, therefore, the greatest bulging occurs in the supraoccipital region. When the jaw position varies, the plane of the resistant base is shifted, and a corresponding shift downward in the cranial bulge is at once evident. Thus, in the Negro, the jaw is decidedly flat and the cranial bulge more nearly reaches the infraoccipital region.

X-Ray Craniometry.—A lateral view of the skull is made, the tube at any distance from the plate. On the forehead of the patient a brass rod, about 2 millimeters in diameter and 25 millimeters long, is vertically attached with adhesive plaster. The exposure is made according to the distance the plate is from the target (20 inches is convenient) and to the current and gap used. In the finished plate, the length of the brass rod is measured and a proportional fraction showing the amount of distortion between 25 millimeters, the original length of the rod, and the measured length on the plate is formulated. This error due to ray convergence may be applied to all measurements subsequently made upon the plate, thereby correcting the values so that they represent true measures. If greater accuracy is desired, two rods, one of aluminum and the other of brass, the same length and 3 millimeters apart, are fastened with adhesive to the median line of the forehead and parallel thereto.

The finished picture must show only one rod, indicating that the superimposition was perfect and therefore minimum distortion attained.

Having procured the sagittal view of the skull, the nasion or naso-frontal junction and the very middle of the sella turcica are marked. A line is drawn connecting the nasion and central sella turcica point, the line extending well in front of the nasion and well beyond the occiput. The distance between the nasion and the outside occipital point on the line just drawn is compassed and divided in half. The half point represents the locus of force distribution and is marked C. (See Fig. 14.) This x-ray horizontal is the base for all measurements subsequently to be made.

X-Ray Jaw Angle.—Camper, using the facial angle, arrived at the observation that as the facial angle reduces, and the jaw more nearly approximates the horizontal, intellectual debasement in animal scale is indicated. Camper's facial angle is dependent entirely, as has been shown above, upon

FIG. 14.—Newly introduced x-ray horizontal drawn from the nasion through a point in the middle of the sella, showing also the jaw angle NCP wherein N is the nasion; C is the mid-point on the x-ray horizontal; and P the prosthion. Showing also total jaw angle NCG where G is the gnathion.

the basal plane orientation in relation to the jaw bone. If the superior maxilla is shallow, the occiput is prominent, the force plane having been shifted to the horizontal. So that, a more perfect measure of the facial angle equivalent is the angle produced by the superior jaw with the x-ray horizontal. A line is drawn from C , the locus of force distribution, to P , the prosthion or point furthest out on the alveolar process of the upper jaw. The angle made by these two lines, the horizontal and the CP , is the x-ray jaw angle. It is normally (640 Americans), 35 degrees. In prognathia, the x-ray jaw angle becomes 30 degrees, or less; in orthognathia, the x-ray jaw angle becomes 40 degrees or more. At first thought, and without x-ray confirmation, it may be thought that prognathia yields a greater jaw angle than orthognathia; but the study of even a few cases will show the reverse to be true in x-ray pathology. That is, extreme prognathia, a stigma of degeneration, is manifested by an approach to the hori-

zontal, both measured according to x-ray standards.

X-Ray Total Jaw Angle.—It is sometimes useful, especially in studying skull changes incident to acromegaly, to have the total jaw angle measure. That is, the measure of the angle formed by the horizontal and the line connecting C with the gnathion (tip of alveolar process of inferior maxilla). Much may be gained from the total jaw measure, but still more from the relative proportion between the jaw angle and the total jaw angle in any case. This relation may be called the maxillary ratio, and is obtained by dividing the total x-ray jaw angle into the superior jaw angle. The following table shows the constants at the various limits:

	Jaw (upper) NCP	Total jaw NCM	Ratio
Prognathia	30	40	0.75
Normal	35	50	0.70
Orthognathia	40	60	0.66

The study of the angles, by the x-ray, just pronounced, has furnished a deep insight into the changes induced by endocrinopathies upon skull conformation. To enumerate the results obtained would occupy more space than it is desired to afford to this general topic of craniopathies; and they will therefore be discussed separately.

It has been shown that an intimate relation exists between the jaw angle and the skull rotundity. The relation may be graphically reproduced in the form of a craniogram as follows: the compass is placed with one leg at C and the other at the prosthion. When this diameter is obtained, the compass is swung to the horizontal extending anterior to the nasion and a semicircle drawn around the skull contour to the horizontal at its projection beyond the occiput. The compass is then closed exactly one-half of the C P diameter and a second semicircle inscribed within the skull. With C as a center, radii are drawn to the outer circle, each radius 10

made to the first one, the distance between the two being exactly the distance between the outer and inner circles in the x-ray. The two parallel horizontal lines are connected by vertical lines the same distance apart as the radii in the outer circle of the

FIG. 16.—The craniogram reproduced on a flat basis. The long sides of the rectangle are the same distance apart as the semi-circles A and B in Fig. 15. The vertical radii are the same distance apart as the radial distance on the arc A in Fig. 15. The upper irregular line is the curve of the upper table. The lower irregular line the curve of the inner table. A is the frontal sector; B the bregmal; C the supraoccipital and D the occipital and infraoccipital. The diagram is from a normal skull and much reduced.

x-ray plate. On each vertical line, corresponding to a radius, two points are marked; first, the distance from the lower line to the point on that radius at the inner skull table; second, the point on the outer skull table. When all the points are marked, the upper set is connected with straight lines, and similarly the lower set. The resulting drawing represents a reproduction of the inner and outer table curves translated to a flat horizontal basis instead of a curved basis as in the original x-ray. (See Fig. 16.)

It is noticed that four sectors are characteristically predominant in the craniogram. The first sector shows a widening between the two curves, the outer more bulging than the inner. In normal craniograms the first sector usually occupies from three to four radii. It corresponds to the frontal sinus. The second sector is the bregma sector. There is usually a widening, though to a much less degree than in the first sector, between the two curves. It corresponds to the frontal region. Then there is the third supra occipital sector. In this the curves are quite parallel to each other and to the base lines of the craniogram. The last sector is the occipital and infra occipital bulge. The two curves are somewhat widened, both arching a trifle when compared to the horizontal.

An important feature of the craniogram is the relative position of the two curves in the rectangle. The more the two curves approach the top horizontal, the greater the degree of orthognathia indicated; the more they approach the bottom horizontal, the greater the degree of prognathia indicated.

From the viewpoint of x-ray pathology, at least, the craniogram presents an excellent feature in its favor; each craniogram is its own standard. The actual size of the craniogram may be compared to any other craniogram and direct skull proportions thus arrived at. True, it is time consuming to prepare a craniogram; but it is done entirely without fatigue on the part of the patient, who, after the x-ray exposure, may be dismissed.

SELLA TURCICA.—Someone has expressed with homeliness, if not with aptness, that scientists, according to their method for classifying phenomena, may be divided into two schools: the "lumpers" and "splitters." It would seem that x-rayists, in the question of classification of normal sella turcica (Turkish saddle) can similarly be divided into two groups: the "lumpers," who describe nine normal types of sellas, and the "splitters," who describe

FIG. 15.—Illustrating by diagram the production of the craniogram. The distance from A to C is the distance from C to P; the distance from B to C is one-half the distance from A to C. The radii are 10° apart.

degrees apart from the other, making 18 divisions in all. (See Fig. 15.)

Craniogram.—When the radii are drawn, as indicated, a straight line is reproduced on a separate sheet of paper. A second parallel straight line is

700 normal types of sellas. That various types of sellar conformation may be visualized in individuals who present no obvious deviation from the normal, it is admitted; but it seems doubtful that as great a number as 700 distinct variables might occur; so that for purposes of *x*-ray pathology the classification tendered by C. Harvey Jewett will be referred to. Dr. Jewett describes the nine groups as follows:

Group I showed structurally long, slim, curved posterior clinoid processes with absence of anterior clinoid processes. This group closely simulates Group III, except for the fact that the latter has a small light anterior clinoid process. It is noteworthy that the statistics of this group show the lowest average age (with the exception of one other group of the same age) and the highest average measurements of the sella, both horizontally and vertically, and the highest average antero-posterior cranial measurement.

Group II shows nearly vertical light weight posterior clinoid processes with wide open infundibulum and absent or extremely indistinct small anterior clinoid processes. This group is similar to Group VII, the latter having distinct anterior processes. The statistics of this group are not distinctive, except for the fact that it contains the largest number of cases.

Group III, as noted above, is similar to Group I, except for the presence of small, light, anterior clinoid processes projecting horizontally backward. The small size and the direction of these processes are the only definite distinctions between this and Group VII. There are no distinctive features regarding the statistics.

Group IV is characterized in general by a very heavy anterior clinoid process, projecting directly backward and occupying a somewhat lower level than the tip of the posterior processes. The group might also be considered similar to Group VII, except for the difference in the construction of the processes. The average height in these cases is the greatest.

Group V gives the appearance of a shallow floor with very indistinct thick processes and wide infundibular spaces. The statistics show this group to be of the highest average age.

Group VI gives the appearance of complete bridging over of the sella turcica, most of the cases showing heavy processes. It is possible that slight rotation of the head might show a different picture, but this was not observed in several cases that were repeated. The appearance of bridging over in this case is undoubtedly due in most instances to the superimposing of shadows. It is interesting to note that the measurements of the sella turcica are the smallest in this group, and that as many as 10 per cent. of the 100 cases studied showed bridging over. This group also shows the shortest longitudinal and the longest vertical cranial diameters.

Group VII, as previously mentioned, closely simulates Group III, but the most distinctive cases of this group show anterior and posterior clinoid processes of about equal length with small infundibular spaces. This group is characterized by the greatest weight and the shortest height, with the exception of Group IX, in which the height is the same.

Group VIII, as cited above, is similar to Group II, having thin, nearly perpendicular posterior clinoid processes, with wide infundibular spaces; but this latter group, in addition, has small but distinct anterior processes. Like Group II it contains a large number of cases. The average weight is the lowest.

Group IX is composed of nine cases, nearly all of which are different, and all of which show great variation. One case is very shallow, and shows complete absence of both processes. Three cases show double anterior clinoid processes with considerable variation in the rest of the sella. Two of these cases were repeated, thinking that position might play a part in the variation, but the same picture was observed. This group shows next to the smallest longitudinal, and the smallest vertical cranial measurement.

In eliciting *x*-ray pathology of the sella two *x*-ray positions are used. The first is a sagittal view by which an exact profile of the saddle is sought. The

second, a stereoscopic view, the tube tilted somewhat eccentrically from the side and above (as recommended by Cushing) in order that the finished stereoroentgenogram may admit of a visualization into the fossa. Profile radiographic measurements that exceed 15 millimeters in long diameter and 10 millimeters in depth may be considered as indicating sellar enlargement. Keith gives for the normal measures 10 to 12 millimeters antero-posteriorly 14 to 15 millimeters transversely and 18 millimeters in depth. These measures are skeletal; and in producing *x*-ray plates for sellar measures, either a correction should be applied determined as described under the caption "Craniometry," or teleroentgenographic plates may be used, according to the method of Jewett. Fitzgerald pointed out that the total length of the skull base, and therefore the *x*-ray horizontal described previously, is a criterion for determining the position and size of the hypophyseal fossa. It has been shown before that the center about which the forces determining the skull conformation operate is closely situated in the region of the sella; so that, reasoning from cause to effect, it would be more proper to say that the position and size of the sella determine the *x*-ray horizontal and ultimate skull conformation (the converse of Fitzgerald's postulate). In a series of 80 college students between the ages of 18 and 32 and certified free from obvious pathology after clinical inspection, the following dimensions were obtained for the average sizes, of the sellas: length, 10 to 15 millimeters; breadth, 14 to 17 millimeters; depth, 7 millimeters.

Tumors of the Hypophysis.—These may be divided into two groups: (1) the intrahypophyseal tumors, (2) the extrahypophyseal tumors. The first variety arise from the hypophysis itself and develop within the sella turcica. These are most often associated with the clinical picture of acromegaly. The second type arise at the entrance to the hypophyseal fossa, and grow above the sella turcica. Clinically, this latter type of tumor is common in Fröhlich type of dystrophia adiposogenitalis. Both kinds of tumors cause changes in the sellar conformation, the intra sellar tumors enlarging the hypophyseal fossa practically evenly in all directions, with incident thinning of the bony structures composing the sella. If the intra sella tumors grow eccentrically the various pathologic erosions of the structure may be visualized; in sagittal plane, if the tumor erodes more on the left than on the right, a sinistrolateral *x*-ray plate will reveal two levels to the sellar floor, the higher true level, and a lower step caused by the burrowing of tumor erosion. Schematic representations of the various sella anomalies are reproduced in Schüller's Atlas and Text, to which reference is made for detailed study of sellar disturbances.

Cushing describes three types of pathologically deformed and enlarged sellas distinguished on the *x*-ray plate. Says Cushing:

(1) Those associated with thickening of the clinoid processes and dorsum cippi; (2) those with thinning from pressure absorption of these parts, and (3) those with more or less destruction of all outlines.

The First Variety.—Here the enlargement is accompanied by thickening of the walls, and as this type is confined to the cases of acromegaly and gigantism which are uncomplicated by adenomatous struma forma-

tion, it is probable that the bony thickenings are merely a feature of the tendency toward osseous overgrowth. In one instance there had been such a degree of bony overgrowth as to mask the actual enlargement of the sella until this was made evident by stereoscopic plates.

Unquestionably, in almost all cases of acromegaly and gigantism, even without the secondary tumor formation, certain evidences of pressure atrophy of the sellar dorsum and base will occur, for a process of bone absorption always accompanies the osteoformative process.

The Second Variety.—Marked thinning with perforations of the sellar floor as well as of the dorsum may occur in acromegaly, but such a condition is comparatively rare in this disease unless the hypertrophic gland has undergone the terminal metamorphosis into an adenomatous struma.

These great distentions with absorption of bone from pressure atrophy are far more common in the cases of advanced hypopituitarism associated with a primary glandular struma. In the earlier stages there occurs a simple spherical distention; whereas in the advanced stages there is an extreme spherical ballooning out of the fossa, which projects far into the sphenoidal cells, the bony capsule being so thin as to cast a hardly perceptible shadow.

The Third Variety.—In these there occurs a more or less complete absorption of the dorsum and a downward dislocation of the base, so that the sellar landmarks, with the usual exception of the anterior clinoid processes, are effaced. This change may be brought about either by the transformation of a primary glandular hyperplasia into the type of malignant struma which is capable of bursting its dural capsule and invading the cranial chamber, or conversely by the downward pressure of an interpeduncular growth which deforms and absorbs the subjacent sphenoidal bone by its progressive enlargement.

Neither of these processes, however, is incompatible with the preservation of a fairly distinct sellar shadow of average size, though the walls are apt to be thinned and show erosions. It may be exceedingly difficult in some cases of this type to identify the outlines on a single plate, the more so since there is apt to be a general downward displacement of the entire sphenoidal region. Hence many exposures from different angles may be necessary, and it is not an uncommon experience, after several plates have shown a supposedly complete absorption of the dorsum sellae, to unexpectedly secure a negative on which the fine line of a thinned and elongated dorsum is clearly apparent.

The chief difficulty in radioscopic interpretation is unquestionably met with in these cases of superimposed extrapituitary growths. Only when the growth has led to a marked sellar deformation are the x-rays of great diagnostic value in cases of this type, for we have seen that the sella may be fairly well preserved, even though the tumor is enormous and has been of long duration.

Equally important, and more difficult to interpret, are the abnormally small sellas which accompany the primary glandular hypoplasias of the young. It has been our experience in these conditions that unusually heavy shadows are cast, particularly by the dorsum sellae. Exceedingly small fossae are occasionally seen.

PINEAL GLAND.—It seems that the pineal gland may be pathologically abused without incident clinical manifestations in many cases, and in still other cases cysts, tumors, and calcification of the pineal body may disturb the endocrine balance of the internal secretions with resulting clinical symptoms such as increased intracranial pressure, certain focal symptoms and signs of disturbed internal secretions of the hypophyseals. In x-ray pathology calcified pineal glands may be noted and the clinician left to determine whether the anomaly stands in etiologic relation to the pathogenesis of the clinical condition studied.

In including a sketch of x-ray pathology of the skull mention must be made of the method of Dandy advanced for the localization of the elimination of

the presence of cerebral tumors through the expedient of ventriculography. The conclusions arrived at by Dandy and expressed in *Surgery, Gynecology and Obstetrics*, xxx, No. 4, are:

1. Ventriculography is invaluable in the localization of obscure brain tumors. So-called unlocalizable tumors comprise at present over half of the total number.

2. Practically all brain tumors either directly or indirectly affect some part of the ventricular system.

3. Hydrocephalus is easily demonstrable by ventriculography and when present usually, though not always, restricts the location of the tumor to the posterior cranial fossa—that is, the brain stem or the cerebellum.

4. Local changes in the size, shape, and position of one or both ventricles as shown by the ventriculogram will accurately localize most obscure tumors of either cerebral hemisphere.

5. Every effort should be made to localize the tumors before resorting to any operative procedure.

6. The usual subtemporal decompression is useless and dangerous when a hydrocephalus is present—that is, when the tumor is in the brain stem or cerebellum.

7. A suboccipital decompression (cerebellar operation) is extremely dangerous when the lesion is in the cerebral hemispheres.

8. To differentiate between cerebral and cerebellar lesions is frequently one of the most difficult tasks in intracranial localization. Ventriculography at once separates these two groups and indicates the operation of choice.

9. The only cure for brain tumor is extirpation. The results in terms of complete cures of brain tumors will be in proportion to the early localizations which are made. A decompression is a purely palliative procedure and should be adopted only when the tumor cannot be located. Ventriculography permits of an early and accurate localization of the growth when all other methods fail.

10. It is possible to get a separate profile ventriculogram of the whole of each lateral ventricle. Any change in size or contour is easily demonstrated. Antero-posterior views will show the same points in cross section, but they are chiefly useful in showing any lateral dislocation of the ventricles.

11. The results in localization of five types of cases of brain tumor are shown with ventriculograms. In all but one of these, the ventriculogram was the only means by which a positive localization could be made. One tumor occluded a lateral ventricle and dislocated both lateral ventricles. Another tumor altered the size and shape of one lateral ventricle. In a third case a cerebral tumor, though suspected, was eliminated by the hydrocephalus. In a fourth case a unilateral hydrocephalus was demonstrated.

12. Occasionally the size of both ventricles is so reduced that air cannot be safely injected. In one case the dislocated position of both ventricles, which were greatly reduced in size, made the localization possible.

13. Ventriculography is also useful in precisely localizing the growth. This permits of an exploration directly over the tumor and greatly simplifies the operative procedures.

14. Many useless and harmful operations will be spared the patient by a judicious use of ventriculography.

15. Doubtless the type of tumor will often be indicated by the ventriculogram. Such knowledge will be useful in prognosis and in determining whether radical or palliative operative treatment should be instituted. These determinations will result from accumulated experience in the correlative operative findings presented in a large series of cases.

16. With experience and care in the use of ventriculography, I believe few tumors will escape accurate localization.

It would seem that ventriculography stands in the same relation to the brain surgeon that pneumoperitoneum does to the abdominal surgeon and diagnostician. In two cases recently studied, ventriculography afforded proof positive of the localization of a tumor, subsequently verified by necroscopic findings.

FALLACIES IN THE DIAGNOSIS AND TREATMENT OF SOME GENITOURINARY CONDITIONS.

By PHILIP S. ROSENBLUM, M.D.,

PHILADELPHIA, PA.

INSTRUCTOR IN UROLOGY, THE GRADUATE SCHOOL OF MEDICINE,
UNIVERSITY OF PENNSYLVANIA.

This subject is being presented with the view of emphasizing the fallacies which have actually occurred in cases during my observations in the Army, in hospitals, and in private practice, and to help avoid their repetition if possible.

Diagnosis of Gonorrhea for Complicated Balanoposthitis.—Whenever a phimosis complicates balanitis of balanoposthitis, there may be and as a rule there is, a thick creamy or pus-like discharge from the preputial orifice. Some of these cases have been diagnosed gonorrhea, based on the presence of the discharge and on the fact that, when performing the two-glass test, the urine trickles down, washes away the pus in the preputial orifice, and consequently clouds the first urine.

Diagnosis of Gonorrhea for Phosphaturia.—Not all cloudy urine is due to pus and not all pus is due to gonorrhea. In this case also, simply because a two-glass test showed both glasses of urine to be cloudy, a diagnosis of gonorrhea was made. The causes of cloudy urine should be borne in mind and in every case phosphates should be eliminated.

Urethral Discharge.—Too much emphasis cannot be laid on the fact that many cases have been diagnosed gonorrhea simply on the presence of a urethral discharge. Snap-shot diagnosis and the slight regard for the venereal infections on the part of many practitioners seem to be the important causes of this hasty conclusion. The time has now come when a microscope in a physician's office is just as essential and indispensable an article as the stethoscope or sphygmomanometer. Just an extra three minutes to stain a smear, with a little more attention to eliminative diagnosis, and these mistakes would not have occurred. The following cases of urethral discharge were diagnosed as gonorrhea: 1.—Intra-urethral chancre. 2.—Tuberculosis of kidney, complicated by tuberculous epididymitis. 3.—Bilateral pyelitis with a mild grade of cystitis. 4.—Chemical urethritis. 5.—Colon infection of prostate with abscess formation, and rupture into the urethra. 6.—Eritismic urethritis, due to excessive coitus or ungratified sexual desire. In these cases the possibility of a concomitant Neisserian infection was carefully excluded.

The Two-Glass Test.—The test most commonly known and the one generally used by most physicians is the two-glass test. Interpretation: First glass cloudy and second glass clear signifies an anterior urethritis. Fallacy: With very little discharge from the posterior urethra, no pus may make its way back into the bladder and a posterior urethritis may thus escape detection. Furthermore, the fact that a posterior urethritis exists may readily be verified by a urethroscopic examination. Both glasses cloudy signifies an anteroposterior urethritis. Fallacy: When very little urine is voided, the anterior urethra may be imperfectly cleansed and a simple anterior urethritis may be mistaken for one of the whole canal.

A Not Infrequent Occurrence Is the Existence of Prostatitis and Seminal Vesiculitis With Perfectly Clear Second Urine.—This is found particularly in chronic cases and sometimes at the terminating stage of an acute attack of urethritis. This condition may readily be verified by massaging the prostate and vesicles and by examining the moist secretion under the one-sixth objective lens for the presence of pus. Thorough irrigation of the urethra before massaging the prostate is essential in order to exclude contamination of the prostatic secretion of pus and bacteria from the urethra. Errors in diagnosis which are commonly those of failure to search for the gonococcus by smear and culture and for absorption by the complement fixation test, are largely responsible for many uncured cases of anterior and posterior gonococcal chronic urethritis, as treatment is prematurely discontinued, even by the physician. Too much stress cannot be laid upon the importance of this fact, for many cases of gonorrhea are discharged as cured when simply having clear urine, without examination of the prostatic and seminal vesicular secretion. This is one of the most regrettable mistakes, since most of the chronicity and latency of gonorrhea is due to prostatitis and seminal vesiculitis.

A Very Frequent Error Is to Consider the Prostate and Vesicles Normal on Simply a Negative Digital Examination.—This is an absolute fallacy since many prostates whose size, contour, and consistency are normal to the touch, yet on massage and examination of the moist specimen show disease to be present.

Similarly, in Senile Hypertrophy of the Prostate Examination of the Prostate, Per Rectum, Ofttimes Does Not Give a True Index to the Obstruction Present.—The degree of urinary difficulty due to prostatic obstruction does not of necessity bear a fixed relation to the size of the gland as felt per rectum. Thus, a small prostate may cause great obstruction to the stream. A small fibrous gland oftentimes gives much more trouble than a large adenomatous gland. The most accurate method of determining the manner and extent to which the prostate encroaches on the bladder is by cystoscopy.

It Is a Fallacy to Rely Upon One Examination of Prostatic Secretion.—Frequently noticed is the normal microscopic appearance of the prostatic and vesicular secretion on the first examination, but, on the second or third examination many pus cells may be present and the true condition of the gland revealed. This may be explained in several ways: either the drop on the first examination happened to contain only the normal elements, or better, the first massage loosened the plugs of pus in the diseased prostatic tubules, only the contents of the normal tubules being evacuated, while on subsequent massaging the previously loosened plugs of pus are expressed.

Complete Emptying of Bladder.—In chronic distention of the bladder with a history extending back over a long period it is a great fallacy, in complete retention, to empty the viscus completely. It is better to tie in a catheter and take seventy-two hours to evacuate completely. Many an unexpected and unexplained death has followed quick and complete emptying of the bladder.

Diagnosis of Chancroid for Chancre and Vice Versa.—The more genital sores observed, the more convinced is one that an absolute positive diagnosis of chancre or chancroid on just the clinical appearance of the sore is impossible. Too many cases have been diagnosed chancroid with subsequent appearance of secondaries or a positive Wassermann reaction. As we all know, an early diagnosis of syphilis is of major importance. By early is meant before the blood Wassermann ever becomes positive. This is the ideal time to treat syphilis, and where anti-syphilitic treatment gives the best results. It is almost criminal to wait for the appearance of secondaries in order to make the diagnosis. An extra five minutes is certainly well spent for a dark field examination in deciding so important an issue.

The Wassermann Test.—So much may be said about the Wassermann test that time will not be taken to discuss fully this important subject. Suffice to say, that it is to be much regretted that so important a test, with its numerous modifications from time to time, should not be performed in an identical manner by all laboratory workers. The only solution offered at the present time is to choose the laboratory in which one has the most faith and to send all specimens to it. In trying several laboratories one may get a variety of findings which will tend to shake one's faith in the value of the Wassermann test.

Some Fallacies in the Interpretation of the Wassermann Test.—(a) Relying upon one negative blood test during the stage of the initial lesion. In one case under my observation the blood Wassermann was not positive for five weeks after the appearance of the initial lesion. Craig gives the incidence in the several weeks of the chancre as follows: First week, 36.3 10 per cent.; second week, 59.3 10 per cent.; third week, 68.9 10 per cent.; fourth week, 77.2 10 per cent.; fifth week, 81.3 10 per cent. One can readily see where an ulcer has healed and a dark field examination is impossible, a Wassermann test should be repeated at intervals of a week for at least a month. (b) Relying upon the result of a Wassermann test while the patient is under anti-syphilitic treatment. Mercury and arsenic interfere with the Wassermann reaction, therefore, it is inadvisable to take blood for a test within a month or six weeks of the administration of treatment.

The Long Held Opinion That Syphilitic Involvement of the Cerebrospinal System Occurs Only After Several Years Has Been Proven Erroneous.—Such an involvement may occur within the first year, therefore, where the blood Wassermann is negative examination has not been complete until a spinal Wassermann has also been performed.

As regards fallacies made in the treatment: 1. The use of too irritating agents in the treatment of gonorrhea. We cannot hope to sterilize the canal with our strong germicides and consequently the irritation produced by the strong remedies traumatizes the tissues, lessens their resistance, opens up new avenues for infection and protracts the course of the disease. 2. Too early medication of the canal in so called bull-headed or Russian clap, where the discharge is bloody and considerable edema present. It is best to wait until the very acute inflammatory symptoms subside before treat-

ing the canal. This procedure will certainly obviate complications and save the patient much discomfort. 3. Too early instrumentation. This predisposes to infectious elements being inoculated upon other parts, not only by the instruments themselves, but also by the slight traumatism absolutely unavoidable which opens the door to extension. 4. Massage of an acutely inflamed prostate, if the patient stands for it. An epididymitis is certainly inevitable. 5. Too frequent massage of the prostate and vesicles. One patient has recently come under my observation with a beginning abscess of the prostate who had been massaged every day. No good can be derived from this procedure compared to the harm done. Twice weekly and at most three times is sufficient. 6. Encouraging external opening of periurethral abscess. One of the most difficult and troublesome conditions to heal without a plastic operation is a urinary fistula, the result of a folliculitis and periurethral abscess. To obviate this complication a periurethral abscess should be opened from within through the urethroscope. Two such urinary fistulae have recently come under my observation in which the abscesses were poulticed and encouraged to open externally. 7. Urethral medication during an acute epididymitis. All urethral treatment during an acute epididymitis should be stopped and is distinctly contraindicated; nevertheless, men continue to prescribe and administer urethral medication during such a stage. 8. Failure to treat foci of infection during gonorrheal arthritis. The prostate and vesicles are the usual foci of infection in gonorrheal arthritis. Time and time again all kinds of therapeutic measures are applied to the joints and vaccine therapy is used without paying any attention to the urethra, prostate or vesicles. 9. Fallacy of the routine method in the treatment of syphilites. To my mind more judgment and less routine should be used in the management of syphilites. Arsenic and mercury per se do not cure syphilis. Up-to-date various routine methods have been advocated, *e. g.* as regards the number of courses, the intervals between courses, the number of injections of salvarsan that constitutes a course, mercury along with salvarsan or mercury following salvarsan. Any one of these methods may be employed, provided one increases the patient's resistance and body power to overcome the infection, but continuing the treatment just as a routine where the dose may be too large for an individual, where the patient develops jaundice, or where an injection has caused marked kidney irritation, certainly defeats the purpose sought by depressing the tissues and reducing their combative powers.

Conclusions.—Each fact and fallacy mentioned represents a specific case or cases which have come under my observation. Most of the fallacies made in the diagnosis of these genitourinary conditions were due:

1.—Too little attention paid to eliminative diagnosis.

2.—Failure to take advantage of the laboratory aid in the examination of the urine, exudates, and secretions.

Most of the fallacies made in the treatment were due to the disregard for one great scientific principle, namely, acute inflammatory conditions at any

focus of the urogenital tract indicate rest and freedom from intervention except in extraordinary circumstances.

Medicolegal Notes.

Care of Viscera Kept for Analysis in Homicide Cases—Admissibility of Evidence of Result.—In a recent prosecution for murder by furnishing the deceased with poisoned whiskey, the Missouri Supreme Court holds that in order to admit testimony showing the result of the analysis of the deceased's stomach, which had been carelessly kept in an unfastened glass jar for several days before it reached the analyst, it was necessary to satisfy the court of the identity of the stomach examined with that of the deceased and that it was in the same condition when examined as when removed from his body. It was not necessary that it should have been hermetically sealed so as to be inaccessible to anybody; it was not necessary to show that there was an entire absence of opportunity for anybody to tamper with it; it was only necessary to show the circumstances were such as to establish a reasonable assurance that it was the same and in the same condition. It was not preserved with that care which should characterize the conduct of an officer in such a case, and the glass jar containing it was carted around in a careless sort of way; but there was no time when anything occurred to suggest a suspicion that the stomach was molested or that any one who might be interested in tampering with it knew that the prosecuting attorney had the jar in transit in his automobile during a day and night on his way to the analyst. It was held that the evidence was admissible. Other similar cases include *State v. Van Tassel*, 103 Iowa, 6, 72 N. W. 497, where the organs of a deceased were shipped by express direct from Nashville, Iowa, to Chicago for analysis. The testimony of the chemist who made the analysis was held admissible in evidence. In *People v. Bowers* (Cal.) 18 Pac. 660, jars which contained the stomach and contents of the intestines to be examined were covered like preserve jars and wrapped in paper, but were not sealed at any time, and afterward were locked for two days in the laboratory of Cooper Medical College, to which the physician and janitor had access. It was then held that the evidence as to the result of the analysis was admissible. The court noted that there were no circumstances tending to show that the jars had been tampered with. Where internal organs were removed by the undertaker and placed in a galvanized iron vessel covered over with a piece of cloth, and passed through three or four different hands before reaching the chemist who made the examination at the expiration of two or three days, the evidence of the chemist was admissible. *State v. Daly*, 210 Mo. 675, 677. In the case of *State v. Thompson*, 132 Mo. 321, 34 S. W. 31, where a considerable interval of time passed between the sealing of the organs in a jar and the examination afterward by a chemist, the court noted the absence of evidence to create a suspicion that the organs were other than those preserved, and evidence showing the result of the examination was held admissible.—*State v. Smith* (Mo.) 222 S. W. 455.

Parent's Consent Ordinarily Necessary to Operation on Minor Child.—An eleven year old girl was placed by her father in the care and custody of her adult sister, who had had three months' experience in training to become a graduate nurse. The sister took the child to a doctor to find whether an operation for adenoids was necessary. He informed her that an operation would be necessary to remove the child's badly diseased tonsils and adenoids. A date was fixed and they returned with another sister, who had had two years' training as a nurse. After an examination of the heart, an anesthetic was administered and the tonsils and adenoids removed; but before coming from under the influence of the anesthetic the child died. The father sued the doctor and his assistant, relying solely on the ground that the operation was without his consent. The Texas Court of Civil Appeals reversed a judgment for the defendants on the theory that the verdict was unauthorized by the evidence. (159 S. W. 122.) Affirm-

ing this judgment of the Appellate Court, the Commission of Appeals of Texas had under consideration the question whether the sisters as temporary custodians of the child had the right to give consent to the operation; or whether the physicians' act in performing it was justified, regardless of the parent's consent, upon the ground that the paramount interest of the child demanded the operation. The authorities are unanimous in holding that a surgeon is liable for operating upon a patient unless he obtains the patient's consent, if competent to give such consent, or, if not, of some one who, under the circumstances, would be legally authorized to give the requisite consent. If a person should be injured to the extent that he is unconscious, and his injuries of such nature as to require prompt surgical attention, a physician called to attend would be justified in applying such treatment as might reasonably be necessary for the preservation of his life or limb, and consent on the part of the injured person would be implied on the ground of an existing emergency. The evidence was to the effect that the germs, seeping from the diseased parts, and carried by means of the circulation of the blood, permeate and poison the system, and unless arrested by an operation such as was had in this case will eventually undermine the whole constitution and result in death. The evidence showed that there was an absolute necessity for a prompt operation, but not emergent in the sense that death would likely result immediately upon failure to perform it. In fact, it was not contended that any real danger would have resulted to the child had time been taken to consult the parent with reference to the operation. Therefore it was held that the operation was not justified upon the ground that an emergency existed. The physicians, acting in good faith, in assuming the sisters had authority to give consent, undertook to perform the operation, and although it was skillfully performed and without negligence, death ensued, as the result either of the operation or of administering the anesthetic, or both. The sisters were but the temporary custodians of the child, and as such temporary custodians it was held they had no authority to give consent to perform the operation in the absence of an emergency. The parent was the only one who could legally give consent to perform it, and, if not given, the physicians' act in performing it was held a legal wrong. If performed without the consent of the parent it would amount to a technical assault for which the child could have recovered had she survived the operation, and, therefore, under article 4695, Texas R. S. 1911, the cause of action would survive to the parent.—*Moss v. Rishworth* (Tex.), 222 S. W. 225.

Where Rupture from Strain Held Not Within Accident Policy.—An accident policy governed by the California laws insured against loss "resulting directly and independently of all other causes from bodily injuries effected solely through external, violent and accidental means." The Missouri Supreme Court holds that death resulting from rupture caused by accidental strain is not "independently of all other causes" where a cancerous growth was ruptured, and but for this growth the injury could not have happened.—*Campbell v. Aetna Life Ins. Co. (Mo.)*, 222 S. W. 778.

Proof of Malpractice Often But Not Always Possible by Experts Only.—There are some facts pertinent to a malpractice case which may be proven only by the testimony of experts. For example, a nonprofessional observer may not ordinarily diagnose disease; the standards of practice in different schools of medicine must be established by the testimony of experts of those schools; and generally with respect to matters of science or specialized art, or with respect to matters resting upon pure theory, judgment and opinion, based upon reasons familiar only to experts, the opinion of experts is generally the only evidence receivable. But the Minnesota Supreme Court hold that it is not the law that a physician can never be found guilty of malpractice except on opinion evidence of negligence furnished by other practitioners. As said in *Getchell v. Hill*, 21 Minn. 461: "There may be cases where the mode of treatment having been shown, the practical common sense of the jury will enable them to determine that the injury or failure of cure is owing to unskillful or negligent treatment."—*Harju v. Allen* (Minn.) 177 N. W. 1015.

LATENT SYPHILIS IN PREGNANCY.

LATENT syphilis in pregnancy occurs with some frequency and because of the temporary increase in syphilis at the present time, may be expected to occur more often in the future. Syphilis in such cases affects both mother and child and the objects of treatment are to cure the mother and to prevent the child from becoming a congenital syphilitic. Dr. Amand Routh read a paper on the subject before the London Obstetrical Society recently, an abstract of which was published in the *Medical Press and Circular* of Dec. 1. Syphilis is probably more prevalent in Great Britain than in America owing to the fact that a very large proportion of the adult male population served in the army during the war and had favorable opportunities for contracting the disease. Routh points out that the opinion is now accepted by most observers that by some means the infection of syphilis is often held latent during pregnancy, and he advances the following suggestions to explain this latency: (1) As a result of spirillolysis, spontaneous or otherwise, the spirochetes can be broken up into granules. These are infecting agents, being, in fact, spirochetes in the granule stage. The granules are able to develop into the mature organism in a suitable environment, or may become biologically inactive and remain latent for varying periods. (2) Chorionic syncytial ferments are present during pregnancy at the point of interdigitation of the fetal and maternal portions of the placenta. Their action is primarily trophoblastic to enable the delicate chorionic villi to penetrate the uterine mucosa and open up maternal blood-vessels, so that the ovum may find for itself a resting place with nutritive blood spaces around it. As a result of the destructive action of the ferments upon the maternal tissues, so-called syncytiotoxins are formed, but any excess appears to be at once neutralized by the so-called syncytiolysins. If not thus neutralized, maternal and fetal toxemia may become present. (3) The chorionic ferments, or their derivatives, are suggested as being capable of exercising their destructive properties upon the infecting spirochetes and breaking them up into granules. (4) It is further suggested that during pregnancy it is the continued action of the chorionic ferments upon the granules which may render them latent and biologically inactive,

and perhaps in a few cases may destroy them. (5) After the pregnancy, when the chorionic ferments gradually diminish in number in the tissues of the mother and child, the granules, unless already destroyed, may develop into mature spirochetes. (6) The success or failure of the chorionic ferments to protect the mother and child from spirochetal infection would depend upon (a) the virulence of the infection, which tends to diminish, owing to the presence of more maternal antibodies with each successive pregnancy; and (b) the source of the infection, whether "mixed" from both parents, or maternal, in which case infection would be continuously present during pregnancy; or paternal, which might be a single infection, and would therefore be most easily controlled by the ferments. (7) The Wassermann reaction of mother and child appear to be negative if infection has been by the spirochetes in their granule stage, so long as the granules remain biologically inactive and the mature organism is absent.

Routh's theory of the pathology of latent syphilis is ingenious and plausible, that is to say, if the presence of spirochetes is accepted as the primary attribute of syphilis. There are many, however, who believe that the organism of syphilis may exist in other form than that of the spirochete. If Routh's view of the pathology of latent syphilis be correct, then treatment of the condition should be greatly facilitated by the discovery of certain chemical substances by which spirochetes can be destroyed without injuring the tissues. If, then, spirochetes are the offending organisms, the employment of one or other of these chemical substitutes should render the prevention of congenital syphilis well within reach. The question of the validity of Routh's theory and therefore of treatment seems to largely hinge on the point as to whether the spirochete is the only organism or most frequent form of the organism of syphilis. It is generally believed to be, but the matter has not been quite definitely settled.

THE PATHOLOGICAL PHYSIOLOGY AND SYMPTOMATOLOGY OF URONEPHROSIS.

ACCORDING to whether the obstacle to the flow of urine through the ureters is total or partial, permanent or temporary, one of two types of uronephrosis occurs. A closed uronephrosis can be obtained experimentally by complete ligation of the ureter, which results in a closed uronephrosis with acute retention without distention. On account of the increased tension above the ligature the renal pelvis and kidney become congested and distended, while the tumefied epithelium becomes incapable of secreting and undergoes atrophy. The renal functions cease and the organ is transformed into a sac which becomes partially absorbed secondarily. This absorption takes place in Henle's or Bellini's tubules or in the calices and pelvis. Histologically, there is at the outset an intense congestion accompanied by interstitial and

intracavitary hemorrhage. The musculature of the renal pelvis hypertrophies from continued contractions and the tubuli dilate from back pressure. The epithelium is capable of regeneration if the ureteral occlusion is removed in time, but should it persist, the walls become sclerosed, the contractions cease and atrophy succeeds dilatation.

When the occlusion is partial but permanent an open uronephrosis with chronic retention and distention ensues. The renal dilatation is considerable but its evolution is slow. The hydronephrosis progressively increases because the tension is not sufficiently high either to arrest secretion or to favor absorption. However, the urine progressively loses its essential principles. If now this large sac becomes closed—the occlusion ceasing to be partial—the tension will maintain its size; it will not increase because the tension is too high for secretion to take place. Neither will it decrease in volume because the histological elements of the kidneys are too atrophied for sufficient absorption to occur.

The evacuation of a hydronephritic sac may take place intermittently or continuously. In the latter circumstance the urine escapes in jets but in lesser quantity than the amount arriving in the kidneys. When the excretion occurs intermittently the urine escapes from the kidneys only when repletion brings the urine up to the level of the ureteral orifice or when the tension is sufficient to force it through. In certain cases intermittent evacuation is more accentuated, in which circumstance there are attacks of acute retention arising in chronic retention. The ureteral permeability disappears, the sac is in hypertension, creating an increase in the size of the kidneys. Then at a given time the sac empties itself, an abundant polyuria indicating the end of the attack. This represents intermittent hydronephrosis.

A movable kidney may be a cause of acute retention; in other cases the continuity between the renal pelvis and kidney is such that the valve located between the two walls forms an obstacle from the distention of the pocket. In these circumstances a momentary polyuria may, by exaggerating the tension, close the opening of the exit of the urine. At other times, a passing tension of the ureter may temporarily complete the closure of the orifices and, according to some writers, it is a spasm of the ureter or congestion of its walls that plays the principal part. The latter hypothesis can hardly be accepted as probable.

A uronephrosis may remain latent for a long time and is often overlooked until the lesion becomes bilateral and anuria and uremia occur. There are, however, cases where this clinical form is accompanied by very severe pain. Other instances of hydronephrosis give rise to tumor, which at the onset causes no physical or functional disturbance and is discovered only when it has attained a certain size. Hydronephroses

are the largest tumors the kidney can produce and confusion with ovarian cystomata is easy.

Hydronephrosis is an abdominal tumor occupying the hypochondrium and flank, afterwards the iliac fossa. It is everywhere dull on percussion and excepting on the left side the intestine is rarely found above it. The tumor is movable, tense, resistant or even fluctuating, while its outline is distinct. It may be mistaken for an hypertrophied liver or spleen. Finally, there are cases of hypernephrosis in which pain predominates and they are common and closely simulate nephritic colic. If the renal retention is aseptic there is apyrexia. During the painful paroxysms the amount of urine decreases, the normal kidney assuming the functions for both organs and being itself influenced by an inhibition reflex. Hematuria is rare, although it may occur. During the paroxysm the tumor is tender to palpation and at the end there is sometimes a real flood of urine, after which the tumor will be found to be soft.

The association of pain and tumor is pathognomonic of renal tumor, but the nature of the morbid production is less easily surmised, because lithiasis, movable kidney and even the nephritides may give rise to an identical symptomatology. Usually, however, cystoscopy, ureteral catheterization, and the functional examination of the kidneys will result in a correct diagnosis.

HERMAPHRODISM AND INVERSION.

THE relationship between pseudohermaphrodisism and inversion has until recently been quite obscure. The older authors insisted that the so-called atypical sex ensemble had no necessary connection with psychic hermaphrodisism or inversion. Inverts were almost never found to present somatic hermaphrodisism and hermaphrodites were very seldom homosexuals in the ordinary sense, though homosexuality could, of course, be forced by false training. The law consults the individual inclinations in deciding the question of sex. Laignel-Lavastine in *Le Progrès Médical* for October 9, 1920, xlviii, 41, endeavors to establish a classification in which both somatic and psychic factors are recognized. It is necessary to exclude all individuals of absent or very low sexuality, and among these are many hermaphrodites. These show infantile genitals and are very often of substandard intelligence. In orthosexual hermaphrodisism the confusion of the external genitals may cause boys to be brought up as girls, and very rarely girls may be raised as boys. These are known respectively as orthosexual androgynes and gynandroids. There remain the homosexuals in which both somatic and psychic factors are recognized. In the typical invert the subject may be somatically normal, including the external genitals. He may present none or but few of the secondary sexual characters of the opposite sex which, however, originate rather in the psyche than the soma, as the feminine voice and gait. In the genito-somatic-psychic homosexual there may be great variability and a number of subtypes.

The author gives accounts of homosexual androgynes who are quite distinct from orthosexual androgynes. In many of these cases the condition of the gonads cannot be determined, but presumably there is an ovotestis. Examples are given of complete genitosomatic-psychic feminism, in which an individual who presents all the characters of a female is possessed of "testicles." The author does not seem aware of the histological studies of Steinach on the gonads in sex confusion. It is very probable that these women or men, whichever they really are, have an ovotestis in which ovarian internal secretion predominates. In typical cases the woman is to be classed as incurably sterile from a somatic cause. The condition opposed to the preceding is termed genitosomatic-psychic virilism. In theory there should be a complete male with the exception of female gonads, but such a condition has never been shown to exist, and in case such should come to light the gonads would doubtless be ovotestes with predominance of testicular internal secretions. The nearest approach to a complete case would be a virile woman with a pseudopenis sufficient for copulation. A few well-marked cases of this kind have been described, but Hirschfeld with all of his experience never saw a female invert with a pseudopenis.

The author does not seem to be aware of the new teaching of Steinach that inversion is a matter of the minute structure of the gonad and that implantation of a normal gonad will be followed by a transformation of the psyche—at least in the male. This theory, if correct, would greatly simplify the relationship between hermaphroditism and inversion.

DUBINI'S CHOREA.

WITHIN a year a brief history of Dubini's electric chorea in medical literature from an Italian source appeared in the *MEDICAL RECORD*, in which it was emphasized that this affection was not a mere transient phenomenon, but may be found described in Italian literature as far down as the eighties, covering a period of about forty years from its original description by Dubini. Nothing was said of any later cases. But in the *Revista Ospedaliera* for November 15, 1920, x, 21, Bignami reports a case seen by him in 1901 in which the diagnosis was probably Dubini's chorea. This case is given in great detail, including histological studies. Apparently the case was not reported at the time; and in a transcription from the hospital records there was no official diagnosis of chorea or indeed of any affection. But the author now has no hesitancy in making the retrospective diagnosis of myoclonic encephalitis. An exactly analogous case was seen in 1900 in Rome by Sciamanna. These two cases may then be said to represent the transition between the old and new diseases, for the conception of electric chorea had by this time become extinct, while myoclonic encephalitis had not yet been heard from. In January, 1920, Professor Nazari stated before the Academy of Medicine of Rome that the cases of myoclonic encephalitis then prevalent represented a recrudescence of Dubini's chorea. The cases cited above

were sporadic, as no massed incidence of such an affection was evident at this time. We note in the case reported that there were no ocular paralyses, and this is true of the historical malady but hardly true of myoclonic encephalitis of today. Apparently this absence may justify the diagnosis of Dubini's disease rather than encephalitis—at least until the significance of this symptom has been finally determined.

DIABETES IN BEARDED WOMEN.

EMIL WEIL and Pichet discussed this subject before the Société de Biologie on January 8 (*La Presse Médicale*, January 12, 1921, xxix, 4). It is intelligible that hirsutism in women may be part of a pluriglandular syndrome, in the course of which there might develop glycosuria. The author's case occurred in a woman of 38 with well-developed beard, who succumbed to an intense saccharine diabetes. The patient also had pulmonary tuberculosis, the stage and degree not being given. Autopsy showed no tumor of the adrenal and the only glandular lesion was sclerosis of the ovaries. The totality of endocrine manifestations was the male distribution of hair in part (beard), virilism (no details), obesity, diabetes. The relationship is obscure and one can only compare this with similar cases. Tuffier and Guémès have reported cases of hirsutism in which the women showed respectively mild glycosuria and well marked saccharine diabetes. The latter readily yielded to diet and probably should really be regarded as glycosuria. Two other cases of hirsuties in women (patients of Laignel-Lavastine) were examined carefully for sugar in the urine, but although none was ever found, tests for carbohydrate tolerance showed that this was impaired, while artificial diabetes could be readily provoked by injecting adrenaline and tyroïdin. There seems therefore to be an undoubted connection between feminine hypertrichosis and glycosuria, while obesity may also be associated. The rationale of these cases is not entirely apparent, but in virilism we should certainly suspect the adrenals.

News of the Week.

The Typhus Situation.—The outbreak of typhus fever in Trieste, the source of the cases brought to this country, appears to have been completely arrested, no new cases being reported. Emigrants awaiting ships are being kept under the strictest observations for a period of twenty-one days before being allowed to sail. Ex-Surgeon General Rupert Blue recently held a conference with the heads of steamship companies in Paris which resulted in the adoption of strict regulations as regards the inspection and cleansing of all emigrants before they leave European ports. American inspectors at all European ports are ordered to examine second-class passengers as well as steerage. The United States Senate, on February 18, appropriated \$200,000 to be expended by the Public Health Service in equipping the quarantine station at Rosebank, S. I., for handling the immigrant problem at the Port of New York and the Public Health Service has ordered the following officers to report immediately at New York: Passed Assistant Surgeon W. A. Scott, ordered to

Rosebank; Assistant Surgeon R. E. Porter, to Ellis Island, and Surgeon A. H. Holer and Passed Assistant Surgeon M. A. Stark, to Fox Hills (Staten Island) Hospital. The New York Health Department is maintaining strict watch on all emigrants entering the city, not only at the port but at the railway terminals, since it has been found that immigrants debarking at Boston have been reaching New York by rail, and often in unsanitary condition. Three children have been found suffering with typhus in Cortland, N. Y. The children with their mother arrived in New York from Naples on January 4, and went to Cortland on January 13, and three days later the first of the children came down with the disease. The Board of Health of Lewis Run, near Bradford, Pa., believes that there are two cases of typhus there and has appealed to the State Board of Health for instructions. A short time ago Vincent Romenelli and his daughter arrived in the village from Italy. The daughter was sick at the time and died soon after. A brother has since died and two other members of the family are sick. The man's wife and a son died of typhus in Italy a few days before he sailed for America.

Malaria in Russia.—A special despatch from Moscow, quoting Professor Martinsovsky, states that there are 10,000,000 cases of malignant malaria in Russia, and that the mortality is about 3 per cent. of those stricken by the disease. The despatch states that there are but 5,000 pounds of quinine in the country.

Hospital Consolidation Completed.—The court has approved the petition for the consolidation of the Park Hospital, the Demilt Dispensary, and the Clinic for Functional Re-education, New York, into one corporate body. The officers of the new corporation are: President, Dr. W. Gilman Thompson; Chairman of the Building Committee, Dr. Allan Wardwell; Vice-Presidents, I. Wyman Drummond, Dr. John A. Hartwell, and Curaud F. Thompson; Secretary, Elwyn W. Poor. Among those on the medical and surgical staff of the hospital are Dr. Joseph A. Blake, Dr. John A. Hartwell, Dr. Irving S. Haynes, Dr. Carlton Wallace, Dr. Charles L. Dana, Dr. Henry S. Dunning, Dr. John D. Kernan, and Dr. Robert G. Reese.

Smallpox Discovered in Washington Hospitals.—Certain floors of the Washington University Hospital and the Episcopal Eye, Ear and Throat Hospital, Washington, D. C., have been put under quarantine by the Health Department following the discovery of cases of smallpox in both institutions. The first patient was a nurse at the Episcopal Eye, Ear and Throat Hospital, who was taken to the Smallpox Hospital on February 5. She had been in service at the George Washington Hospital in January. On February 14 a patient in the George Washington Hospital was found to have the disease.

British Births Highest Recorded.—According to an official report of the Registrar-General, births in England and Wales during 1920 reached the highest figure ever recorded, and the death rate was the lowest. The birth rate was 25.44 per thousand and the death rate was 12.4. The deaths of infants under one year were 80 per thousand.

The Doctor's Right to Prescribe Beer as Medi-

cine.—The United States Treasury Department has asked a ruling as to whether physicians can prescribe beer for sick persons under the terms of the Prohibition Enforcement act. The reason for this request is that since the recent order of the Prohibition Enforcement Bureau permitting physicians to prescribe wine in unlimited quantities, many inquiries have been received from doctors asking why the right to use beer for medical purposes was denied.

Encephalitis in Detroit.—Health Commissioner Dr. H. F. Vaughan reports that there have been 58 cases of "sleeping sickness" reported to the Detroit Board of Health since January 1. There have been 27 deaths, almost double the mortality from the disease last year. The Health Department has put a special staff of nurses and physicians to work to learn, if possible, the source and manner of spread of the disease.

"Sleeping Sickness" in New York.—From January 1 to February 15 there have been reported to the New York Health Department 179 cases of encephalitis lethargica, and 47 deaths. The Department does not believe that this fairly represents the situation, inasmuch as the disease has but recently been made reportable. The mortality rate from the disease is estimated at 10 per cent. and this would indicate that there have been in the neighborhood of 470 cases since the first of the year. During the week ending February 19 there were 50 cases reported with three deaths. The Laboratory of the New York State Department of Health has turned all its laboratory resources to the effort of discovering the cause of lethargic encephalitis. Physicians throughout the State have been asked to make reports and the department announces that it stands ready to furnish all possible diagnostic assistance.

Lepor Takes Stroll in Washington.—Willard Centlivier, held as a leper in a cottage on the Eastern Branch to the District Building by the Health Department, escaped from his caretaker and took a stroll through the streets of Washington. Centlivier and another patient are said to be dissatisfied because they are kept in a building so small that it does not afford private quarters for each man. The local health department has been promised that these two patients will be transferred to the Federal Leprosarium at Carville, La., but when they will be moved is not known. The Health Department feels that it should not have to care for these men, who are not natives of the District of Columbia.

List of Reportable Diseases Amended.—At its meeting on January 27 the New York City Health Department amended Section 86 of the Sanitary Code regulating the reporting of communicable diseases. The diseases to be reported within twenty-four hours from the time the diagnosis is made now includes the following: Acute anterior poliomyelitis (infantile paralysis), anthrax, Asiatic cholera, botulism, diphtheria (croup), dysentery (epidemic), encephalitis lethargica, epidemic cerebrospinal meningitis, glanders, suppurative conjunctivitis, hook-worm disease, leprosy, malarial fever, measles, mumps, paratyphoid fever, plague, pulmonary tuberculosis, acute lobar pneumonia, bronchial or lobar pneumonia, influenza,

rabies, rubella (German measles, rotheln), scarlet fever, epidemic septic sore throat, smallpox, tetanus, trachoma, trichinosis, tuberculous meningitis, typhoid fever, varicella (chickenpox), whooping cough and yellow fever. If the disease is typhoid fever, scarlet fever, diphtheria, epidemic dysentery, or epidemic sore throat, every such report shall also show whether the patient has been, or any member of the household in which the patient resides is engaged in the handling of milk, cream, butter, or other dairy products for sale or preliminary to sale.

Drug Raiders Make Big Find.—The Narcotic Squad under Commissioner Dr. Carleton Simon, after months of detective work, made a raid on a flat in East Twelfth Street whereby it is believed the center of the organized East Side drug traffic has been reached. After a hand-to-hand fight the squad succeeded in gaining access to this dive, where over \$60,000 worth of cocaine, heroine, and opium were found.

Woman Reaches Ripe Age of 109.—Mrs. Mary Fischer, who would have been 110 years old next May, died of old age in Chicago on February 11. She was born in Poland in May, 1811. Her faculties were clear until a few hours before death.

War Medical Statistics.—The Army Medical School, under the supervision of Col. Charles Lynch, is making progress on a comprehensive medical and surgical history of the war, and it is expected that the first of the volumes will appear about July 1. The work will show how many men from different States contracted any one of the 350 diseases listed, and it will be possible to judge how men from one State stood the military service in comparison with those from others. It will show how long men remained in the service before they had to be taken under medical supervision and ultimately separated from active duty. The statistical data are being prepared in view of the possibility of further legislation affecting war-risk beneficiaries. It will be possible to ascertain, for example, how many men afflicted with tuberculosis came under treatment within specified times and what part the military service played in breaking down the thousands of men that are asking for compensation.

Cancer Cures With State Radium.—Dr. Harvey R. Gaylord, director of the Gratwick Laboratory, where cancer is being treated by radium purchased with the Legislature's appropriation of \$250,000, recently sent his annual report covering laboratory and clinical work to the Legislature. Of 537 cases treated, many apparently hopeless, 358 showed remarkable improvement or could be classed as clinically well. The group of cured cases numbers 202, and the report states that undoubtedly some of the case reported as improved will prove to be permanently cured. The laboratory will install soon the type of x-ray apparatus developed by Professor Duane of Harvard University, which has a penetrating power greater than any used heretofore.

Regulations Requiring Registration of Drug Addicts Revoked.—Walter R. Herrick, Commissioner of the Department of Narcotic Drug Control of the State of New York, has repealed the Special Rules and Regulations for the City of

Greater New York requiring the registration of all drug addicts, promulgated June 25, 1919, to take effect February 14, 1921. This action is taken because the necessity for such registrations has been eliminated by Regulation No. 12 of the new rules and regulations of this department prohibiting the use of unofficial blanks by physicians issuing prescriptions for or dispensing cocaine, opium or their derivatives and by Regulation No. 16 requiring data concerning prescriptions for habitual users to be inserted on the official blanks.

Dr. Percy R. Turnure of New York has had the Cross of the Legion of Honor conferred upon him by the French Government, through General Colardet, for "eminent services rendered to France during the world war."

Dr. Frederick S. Westmoreland has resigned his position in the Bureau of Hospitals of the New York Department of Health to enter private practice in Spartansburg, S. C.

Dr. Stephen Smith celebrated his ninety-eighth birthday anniversary on February 19.

Suicides in the United States Increase.—In its 1920 report the Save a Life League, of which Dr. H. M. Warren is president, states that there were more than 6,000 suicides in the United States last year, more than 1,000 in excess of the number for 1919. Many more men than women wearied of life, there being 3,567 men who destroyed themselves and only 2,604 women. According to the report Dr. F. L. Hoffman estimates that the suicides not reported would have raised the total to 12,000. The economic loss through suicide for the year 1920 is placed at \$10,000,000. Divorce figured prominently in this record of suicides, more than 100 couples killing themselves for this reason. More than 400 soldiers have destroyed themselves since returning from the war. Last year there were 75 presidents and managers of large business concerns, 36 men in the millionaire class, and 23 rich women who terminated their own lives. Doctors supplied the greatest number among the professions, 51; then followed actresses, 40; teachers and college professors, 34; lawyers, 24, and brokers 24. Of bankers there were 59, including 14 bank presidents. Self-destruction among children has reached an alarming situation. In 1919 there were 477 children who ended their lives in this country; in 1920 the number increased to 707—boys 223 and girls 484. About 200 of these children used poison and 150 had recourse to a revolver. The report expresses the opinion that many of these promising lives could have easily been spared if parents and friends had been a little more humane and taken a kindly interest in their welfare.

Bureau of Record of Athletic Events in High Schools.—Arrangements have been made by the Bureau of Education of the Department of the Interior for preserving and publishing records made in athletic events by boys and girls in high schools and in the higher grades of the elementary schools. The work will be under the direction of Professor George E. Schlafer of Indiana University, Bloomington, Ind., and correspondence relating to it should be addressed to him. Blanks to be used in reporting the records to Dr. Schlafer may be had from him or from the Bureau.

Civil Service Positions Open to Physicians.—The United States Civil Service Commission announces open competitive examinations to fill vacancies in Saint Elizabeth's Hospital, Washington, D. C., and positions requiring similar qualifications. The positions open are as follows: Senior assistant physician, at \$2,500 to \$3,500 a year; assistant physician, at \$2,000 to \$2,500 a year, and junior assistant physician, at \$1,500 to \$1,800 a year. Applicants should at once apply for Form 2118, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C. Applications must be filed before March 22, 1921.

Civil Service Positions for Psychiatrist.—The United States Civil Service Commission announces an open competitive examination for the position of Associate in Clinical Psychiatry and Psychotherapy at St. Elizabeth's Hospital, Washington, D. C., and vacancies in positions requiring similar qualifications. The position carries a salary of \$2,500 a year. Applicants must have a bachelor's degree and a medical degree or its equivalent from institutions of recognized standing, at least one year's resident hospital experience, and at least three years' experience in the care and treatment of the insane. Those wishing to file applications should apply at once for Form 2118, stating the title of the examination desired.

Red Cross Volunteers Help in City Hospitals.—Two hundred volunteers, many of them women prominent socially, have come to the rescue of the New York hospitals which have been overwhelmed by an increasing number of patients and a shortage of nurses. The volunteers have been organized into units under the direction of Mrs. Lucy W. Phister, who was active in organizing the Red Cross Overseas Service. Many of these volunteers are already on duty in the wards of various hospitals.

Death Rate Among Industrial Workers Drops.—Statistics based on the records of 16,000,000 persons holding insurance policies in the United States and Canada are considered fairly representative of the general population. The Industrial Department of the Metropolitan Life Insurance Company shows a death rate of 9.7 per thousand, which is 9 per cent. less than the 1919 rate, and 23 per cent. less than the mortality record of 1911. Tuberculosis, pneumonia, influenza and accidents showed a marked decrease. The improvement as regards tuberculosis is most marked. In 1920 this disease was responsible for 13.9 per cent. of the deaths, a death rate 14 per cent. less than in 1919, and 40 per cent. less than in 1911. The influenza and pneumonia death rate was 27 per cent. lower last year than in 1919. While the modern safety movement has been effective in lessening the number of industrial accidents, the automobile accident rate was 10.9 per 100,000, higher than ever recorded before in this group of industrial workers. The suicide death rate was one-half that of the year 1911.

Naphtha-Soaked Soil Said to Cause Sickness.—About four months ago an eight-thousand-gallon tank of naphtha was smashed in a wreck on the Philadelphia and Reading Railroad near the town of Roelofs, Pa., and ran into a nearby pit. About two weeks later an overpowering odor began to rise from the ground and many people in the vicinity became ill. One man is said to have died from

drinking naphtha-tainted water, others were made seriously ill, and practically every one in the town was more or less affected. All the cows on the farm on which the naphtha was spilled became ill.

Gifts and Bequests.—By the death of Alfred Treadway White a number of benefactions made during his lifetime for which the Brooklyn Trust Company was made trustee now become available. Among these are the following: Brooklyn Board of Charities, \$168,000; Visiting Nurses' Association, New York, \$168,000; Brooklyn Children's Aid Society, \$41,000; Brooklyn Society for the Prevention of Cruelty to Children, \$30,000; Brooklyn Hospital, \$17,000; St. Christopher's Hospital for Babies, \$30,000.

New Building for Harvard Cancer Commission.—A new building is being erected adjoining the Collis P. Huntington Hospital in Boston which will be devoted to x-ray and radium work. The insurance companies of Boston have given more than \$30,000 toward the new building.

Obituary Notes.—Dr. ROBERT A. BLACK, who was formerly head of the Health Department of the Boroughs of Brooklyn and Queens, New York, died suddenly in Hot Springs, Va., where he has resided for the past sixteen years, on February 14, at the age of sixty years. He was a graduate of the College of Physicians and Surgeons, New York, in 1883.

Dr. WALTER R. ISZARD, a graduate of the Hahnemann Medical College, Philadelphia, in 1902, died at his home in Brooklyn, N. Y., on February 18. He was genito-urinary surgeon to the Cumberland Street and Prospect Heights Hospitals, was on the staff of the Peck Memorial Hospital, and was visiting physician to the Methodist Episcopal Home for the Aged. He was a member of the New York State Homeopathic Society, the Associated Physicians of Long Island, and the Academy of Pathological Science.

Dr. JOHN J. BURNELL of Greenwich, Conn., died as the result of a motor accident, on February 13, at the age of sixty years. He was a graduate of the College of Physicians and Surgeons, Baltimore, in 1883, and was formerly on the staff of the Roosevelt Hospital.

Dr. LEO RATNER, a graduate of New York University Medical College, in 1892, died at his home in New York City on February 18.

Correspondence.

PSORA?

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Among the "Causes of Death of French Kings" there is one that is not given in the article with this title in the MEDICAL RECORD of Feb. 5. Neither is this cause to be found among those given in Witkowski's book on this subject. It was given at a lecture by the distinguished American medical historian Dr. Jas. J. Walsh of this city, who cited as the cause of death of a French king as given by his physician to be that of "the itch struck in." This omission I beg to record for the benefit of those of scholarly tastes who may see fit occasionally to pass their spare time in studies of this kind and who are alluded to in the article in the MEDICAL RECORD quoted above. HISTORICUS.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, February 3, 1921.

Encephalitis Lethargica.—There has been recently a considerable amount of writing in the press concerning encephalitis lethargica, which is mis-called sleeping sickness. According to accounts which seem to bear the marks of authenticity, the disease is prevalent in most parts of the world and particularly so in Italy and Great Britain. As a matter of fact, the disease, at any rate, in Great Britain, is not present in epidemic form, but there are a good many cases in London and neighborhood. The malady is of great scientific interest and the Ministry of Health have made and are making investigations with the view of elucidating some of its moot points. This much at least is known that it is not very contagious. It is of a low degree of infectivity. As for the mode of infection it appears to have been shown more or less definitely that whatever virus exists is in the saliva or nasal discharge. That it is conveyed by personal infection. There is no specific treatment, it should be treated on general lines. Because so many cases occurred soon after the epidemics of influenza in 1889 and 1918, it was suspected by some of being related to influenza. However, this supposition seems to be ill founded. The disease is notifiable in England, and as said before the Ministry of Health are endeavoring to elucidate the matter. Indeed, this department is about to issue another report on the subject.

Report on Milk in Great Britain.—A report on milk has been published recently in Great Britain prepared by a parliamentary sub-committee appointed by the standing committee on trusts. This report is more of an economic nature than one relating to health or food value of the substance, but contains many features of much interest to American medical readers. With regard to the value of milk as a food, the committee strongly urge the importance of bringing about a substantial increase in the consumption of milk, more particularly among young children. It is pointed out that the regular use of milk in the dietaries of children insures the supply of the food accessory substances or "vitamines which have been shown to be so essential for growth and development. But apart from this special dietetic advantage of milk the ordinary food constituents of which milk is composed exist in forms which are most easily utilized by the human body. These constituents in milk compare favorably in cost weight for weight, with the same constituents in other forms of food, such as meat, fish and eggs. The following is a summary of the conclusions reached: (1) The large combinations of distributors that are in existence have not dealt unfairly with either the producer or consumer up to the present. They have effected considerable economies, and the committee consider that they have operated in the interests of the consumer as well as in the interests of their shareholders. (2) There is still ample room for improvement in the methods of dealing with milk at all stages, both from the economical point of view and also having regard to the health of the nation. The committee recommend that all milk should be delivered in bottles. In order that this may be accomplished,

they consider that either some form of combination among the distributors is inevitable or municipalities should be empowered to undertake the distribution. (3) Combinations of producers and retailers in certain districts have fixed their prices at an unreasonable level, and they consider that all such cases, where complaint is made, should be dealt with under Section 1 (a) or (b) of the Profiteering Act, 1919, and that as a further precautionary measure, the local municipal authorities should be empowered to take over the distribution of milk in those areas. (4) Should the proposed amalgamation of the producing distributing interests in the milk industry mature, they consider that the consumer would require to be adequately protected. (5) There are no combinations, or agreements between manufacturers of milk products, other than the usual dairy produce that is, condensed milk and patent milk foods. There is some diversity of opinion among even prominent medical men as to the value of milk as a food. The committee have a very high opinion of this value, as the majority of medical men have, but there are some distinguished dissentients from this view. Dr. Harry Campbell holds that while perhaps cow's milk is the best, most easily available substitute for human milk, that in fluid form is not at all well adapted for the nutrition of children who have cut their teeth. In the form of cheese it is an excellent food. The report appears to show that in this country there is little or no profiteering in milk.

Sanatorium Mismanagement of Tuberculous.—The *Lancet*, January 29, referring to the published Transactions of the National Association for the Prevention of Tuberculosis, eighth annual conference, alludes to Charles L. Minor's North Carolina criticisms of sanatorium treatment. He contrasts the work done by private and public sanatoriums very greatly to the disadvantage of the latter. He thinks that the public institutions are apt to be exploited by medical officers of the come-and-go stamp as a stepping stone to something better. Speaking from the point of view of the superintendent of a private sanatorium he took the stand that the best arrangements provided separate quarters for advanced, moderately advanced and incipient cases, so that patients in the last class should not hear the coughs or see the coffins of patients in the first class. Sir Henry Ganvain, who spoke at the same meeting, agreed with Dr. Minor as to the failure of sanatorium treatment for the working classes.

Obituary.—Mr. Rupert Farrant, a brilliant young surgeon, who was only thirty-seven years old, has recently died as the result of the strain of strenuous war service. Almost up to the time of his death he was assistant surgeon and lecturer in practical surgery and endocrinology at Westminster Hospital. He had a distinguished career as a student at Westminster School and St. Bartholomew's Medical School. Mr. Farrant was much interested in a study of the internal secretions and made a special study of the influence of the thyroid gland on general metabolism. He twice delivered lectures on this subject at the Royal College of Surgeons of England as Hunterian Professor.

LETTER FROM GENEVA.

(From Our Own Correspondent.)

GENEVA, January 15, 1921.

Sanatoria for Surgical Tuberculosis.—Since the war, tuberculosis has been on the increase in Switzerland, as it has in other countries, but the antituberculous work done so far has been almost exclusively directed against pulmonary tuberculosis. While eleven Swiss cantons possess each an establishment destined for the treatment of pulmonary cases, there exists at present only one altitude sanatorium for surgical tuberculosis, namely, the one that was put up two years ago at Leysin by the Vaudoise Antituberculosis League, and nevertheless, according to the statistics of de Quervain and Hunziker there are no less than 3000 surgical tuberculosis cases per annum in Switzerland. This is evidently a great social injustice that should now be rectified and this has been undertaken by Prof. de Quervain of Berne and Dr. Rollier of Leysin.

Since surgical tuberculosis is, like the pulmonary process, a disease in which the question of soil plays an active part, it is essential to place these patients in the best possible conditions for defense of the organism. An experience of twenty or more years has allowed both Bernhard and Rollier to prove that a mountain suncure fulfills these conditions perfectly, because it affords the most efficacious general treatment, while heliotherapy, combined with rational orthopedic treatment, is for many cases the best local treatment.

Switzerland, with its numerous Alpine and sub-alpine resorts, is better placed than many other countries for organizing an antituberculosis fight for surgical cases of this affection. The advantage of mountain resorts resides in the fact that solar radiation is there most intense and continuous and patients can benefit from the sun during the entire year, an essential factor in the cure. The ideal solution would be that each canton should have its own sanatorium for surgical tuberculosis in a chosen altitude resort. In the case of small cantons several might use the same establishment. It is not a question of building luxurious installations, as at present the cost makes any such undertakings out of the question, but while waiting for better times to come, it is possible to use already existing hotels that have been little frequented since the war and which could be bought or leased under advantageous conditions, and could be altered over into hospitals. The experience gained by the free clinics at Leysin shows that such a transformation is easy to realize. It is important that the sanatoriums for surgical tuberculosis should be independent of those for pulmonary tuberculosis already in existence. The treatment of the surgical cases requires special medical knowledge, not only of heliotherapy but also radiodiagnosis, radiotherapy, orthopedics, and conservative surgery, all of which are precious adjuncts to the solar cure. An organization for occupational cure must be carried out in these establishments. Experience gained in this domain among the Swiss tuberculous soldiers quartered at Leysin allows one to conclude this is a therapeutic, physical, and moral factor of the first importance. It has also the advantage of giving patients the faculty of partially helping toward the cost of their treatment.

In order to maintain and consolidate the cure of tuberculous subjects, it is necessary that when once recovered, they should live in good hygienic conditions. By creating in the plains agricultural, market-gardening, and wine-growing colonies for convalescents, the latter can avoid returning to trades, often unhealthy, or returning to insanitary lodgings. Thus, it may be possible to solve the double social problem: on the one hand, to prevent recurrences, on the other to furnish the nation with labor, which has become progressively scarcer on account of the movement from the country to cities. In order to solve the financial side of the problem, a popular movement will be started in favor of patients with surgical tuberculosis. An appeal to the good sense of the Swiss people will not fall on deaf ears, and the funds collected will be placed at the disposal of the cantonal leagues. The above propositions propounded by de Quervain and Rollier are being examined by the Swiss Association for Tuberculosis and will undoubtedly be favorably acted on.

Although the treatment of already existing surgical tuberculosis appears as an urgent necessity, it is no less important and certainly easier, to organize a prophylactic fight against these affections. Like pulmonary tuberculosis, the surgical forms almost invariably follow a tracheobronchial adenopathy—this first manifestation of tuberculous infection in childhood, so that it is important to arrest further progress of the disease by placing children in the most favorable conditions for organic resistance. This can be accomplished by the introduction of reforms in the hygiene of tenements and schools, in which a larger place should be given for the physical development of the children—schools built in the open and freely exposed to the sun. Such is the present program which is under consideration.

4. A Case of Ovarian Pregnancy. Michael F. Fallon.
5. A Note on Gliomata with Report of a Case. Henry Viets.
5. A Note on Gliomata with Report of a Case.—Henry Viets reports a brain tumor, glioma, of the right temporal lobe, which infiltrated and largely replaced the tissues of the lobe without deformity in the general shape of the brain. A large cyst was formed. The tumor extended to the base of the brain and bulb, where it ran in the subarachnoid space over a large part of the ventral surface of the brain and extended down the spinal cord to the conus terminalis without invasion of any part of the central nervous system except a small portion of the left cerebellum. The medulla and cord were greatly compressed by the tumor mass. The symptoms and signs of both a brain and a spinal cord tumor are recorded with the report of a negative surgical exploration. Both macroscopically and microscopically the tumor showed the characteristics of a malignant glioma. The case illustrates in a striking manner the tendency of glioma to extend along a serous surface without invasion.

New York Medical Journal.

9. Röntgen Ray Therapy in Hyperthyroidism. Walter C. Barker.
10. Thyroid Deficiency in Otolaryngology. James G. Callison.

1. **The Surgical Aspects of Hyperthyroidism.**—John B. Deaver, in closing the discussion of this subject, reiterated that there are few diseases that so easily fall into the medicosurgical class as hyperthyroidism. There is without doubt a justifiable difference as to when medical measures should give way to surgery. In a large class of cases the patients improve and are cured by rest, medication, x-ray, and other measures, but the difficulty that confronts the profession is the inability to tell which patients will and which will not improve without surgical measures and how long to wait before deciding that medical means have failed. If the injunction to the internist is, do not wait too long, the injunction to the surgeon should be, do not rush operation; and unless properly equipped with the physical facilities and surgical acumen and skill, one should hand one's cases over to those who, by their intense study of the question and by their aptitude, have placed thyroid surgery among the safe operative procedures.

2. **Hyperthyroidism in a Child.**—Morris H. Frantz gives the history of a girl nine years of age who presented the symptom complex of hyperthyroidism, the first manifestation of which was noticed by the mother when the child was one and a half years old, at which time a swelling in the neck was noted. Due to the residence of the parents of the child in a goitrous district, the mother of the patient suffering from hyperthyroidism, and the mental precocity of the patient, the question arises whether this condition is congenital.

3. **Thymic Disease.**—Alvin E. Siegel, from the observation of two cases and of others not reported, and from a study of the literature, deduces the following conclusions: 1. Thymic disease is more frequent than is generally supposed. 2. There may be some influence on metabolism and growth from too early or too complete atrophy of the gland. 3. Thymic disease and status lymphaticus are closely allied, and differ principally in the extent of the involvement. 4. Thymic enlargement may be a misnomer because the symptoms may arise with little or no enlargement. While there may be hypertrophy or hyperplasia, difficulty seems to be caused more by hypersecretion or by hypertoxicity of the secretion. 5. The thymic secretion exerts a selective depressant influence on cerebral respiratory centers. 6. Exposure to the x-ray is the best method of treatment. Hypodermic medication and instrumentation of any sort should be avoided.

5. **Behavior of Blood Pressure During the Use of the Stomach Tube.**—C. A. McKinlay, after the occurrence of epistaxis during stomach lavage in a case of arterial hypertension, undertook a brief study of the temporary

effects on blood pressure caused by the passage of the stomach tube. Aside from the known effect of mental excitation, muscular activity and straining, the question presented itself as to the part played by the irritation of the buccal, esophageal, and gastric mucosa in causing temporary increase in blood pressure quite constantly observed. Blood pressure determinations were made in twenty-six cases, studied in four groups, the only selection made being to include cases in which there was hypertension. His conclusions from the study follow: 1. There is, as a rule, an increase in blood pressure of from 20 to 50 mm. of mercury with the passage of the stomach tube. 2. There is a greater increase in those cases in which there is retching. 3. The increase in blood pressure is not dependent on straining or mental excitation. 4. The percentage of increase is greater in cases in which there is hypertension. 5. Cases in which there is hypertension when under the physiological effects of pilocarpine giving vagus inhibitory action show an average increase in systolic blood pressure which is less than the increase when pilocarpine has not been given. Similar cases with diminished vagus inhibition following atropine show no marked variation in the average increase from that noted in cases without atropine.

9. **The Etiology of Common Warts: Their Production in the Second Generation.**—Lyle B. Kingery, in line with the theory that common warts are of infectious origin and that the particular infectious agent is in the nature of a filtrable virus; and following the experimental production by Wile and himself of small papular lesions at the sites of the injections of verruca filtrate made from the ordinary lesions of verruca vulgaris removed by curettement, undertook a second series of experiments with a view of producing these lesions in the second generation. The same technique was used as in the first experiments, and the induced lesions were the source of material. After an incubation of approximately six months, extremely minute papular lesions gradually made their appearance at the exact sites of the injections of the sterile filtrate. One or two of these second generation lesions after a time disappeared spontaneously, the majority, however, gradually increasing in size until they approximated that of a split pea. At that time they presented marked hyperkeratosis, a definitely verrucous surface, and were in every way clinically indistinguishable from ordinary verruca vulgaris. Histological examination at this time revealed a picture virtually identical with Unna's description of the changes occurring in these lesions.

11. **Tumors of the Ovary in Children.**—William A. Downes bases this communication on a case of a large ovarian cyst in an infant seven months old. A lower right rectus incision was made, a trocar was introduced, and 2.5 liters of clear, straw-colored fluid withdrawn. A pedicle, the size of the little finger, springing from the left cornu of the uterus was ligated with No. 1 plain catgut. The right tube and ovary were normal. Convalescence was uninterrupted and the child was discharged from the hospital cured. The writer found in the literature only two cases of tumors of the ovary in children, including cysts, in which the condition was operated on in the first year of life. He makes the plea for earlier operative interference in the surgical diseases of infants and children.

1. **The Surgery of the Spleen.**—Sir Berkeley Moynihan holds that a number of symptoms may draw attention to the spleen, even when clinical examination does not reveal the presence of splenomegaly. It is through the correct insight into the significance of the

clinical symptoms and other morbid phenomena that the real understanding of any supposed case of splenic disease becomes possible. Instead of searching only for the existence of this or that splenic disease, an inquiry should be directed to the determination of the functional capacity of all the various organs likely to be deranged. This derangement must be regarded not merely as a restriction of the morbid changes to the spleen, but as a disturbance of wide ramification throughout the whole body, affecting one or other, or perhaps even all, of the four systems in which the spleen plays a part. The focus, at the moment, may in truth be in the pulp of the spleen; but even so, the general picture presented by the patient is the outcome of the participation of the other systems in the process which started in the spleen. It may be that splenectomy in any of these diseases will remove the obvious culmination of the morbid process, and thus bring about a "cure" of the disease or an arrest of its development; but it does not by any means follow that all the other related parts are thereby caused to return to their normal states. Absence of symptoms does not imply the restitution of normal functions. A further step in the investigation of the clinical condition of the patient should aim at the exact discovery of the site of the lesion in certain particular cell types: (a) in the splenic pulp; (b) in the bone marrow and in any part where the reticulo-endothelial cells may exist in specially congregated or active masses; (c) in the liver; (d) in the endocrine organs, including the pancreas. This lesion being predicted or recognized, the question will arise as to whether it consists in or entails the elaboration of poisons capable of causing hemolysis, cirrhosis, or asthenia. The tissue affected, and the changes therein resulting being recognized, further research must be directed to the discovery of the type of infective agent at work, whether bacillary, spirochetal, or other. In other words, the patient is no longer to be regarded merely as the victim of some type of "disease," but as the victim of disorders of a certain character in certain parts of certain anatomical or functional systems of the body. It is the form of the disorder, the form of distribution (determined by an assessment of the functional capacity of the several organs concerned or likely to be concerned), when correctly studied, that will inevitably lead to the source and cause of the morbid state, and ultimately to the prospect of the "cure" of the patient.

2. Inoperable Uterine Carcinoma Treated by the Cold Cautery Method of Percy.—Percival P. Cole states that the forty-three cases on which this report is based, gauged by whatever standard, from the radical point of view, were inoperable. They were drawn from the chronic wards of the Cancer Hospital. No selection was exercised in the choice of cases in so far as concerned the local condition. Attention was directed to the general condition only, no case being dealt with unless this was sufficiently good to render reasonable the immediate risk incurred. The abdominal wall in every case healed without a trace of suppurative. A striking improvement in the general aspect occurred within two or three days of operation. Slight reactionary temperature may persist for a few days at first; in the writer's cases it caused no more anxiety than that which frequently obtains after a supravaginal hysterectomy. Shock has never been encountered, which is the more noteworthy in view of the fact that several of the patients were more than fifty, and one was sixty-eight. In three cases sloughs of considerable size were passed per vaginam, and in one case the coincident loss of blood was considerable, but it was not repeated. A foul discharge may commence on the third or fourth day and persist about a fortnight. Patients are kept in bed for three weeks and leave the hospital at the end of a month. Vesicovaginal fistula has resulted in seven cases. Twenty-nine of the patients were traced and found to have died, five were untraced, the operation was abandoned in two, and seven were living at the time of the report. Of eight patients who died in the hospital (not discharged) the average length of life after operation was $3\frac{1}{2}$ months; of four who died in the hospital after readmission, average one year and eight months; of seventeen who died outside, average one year and four months. From his experience Cole considers that this operation, particularly when rein-

forced by subsequent radium treatment, should have a place in the armamentarium of a surgeon who would endeavor to undertake the treatment of inoperable cancer. With the cautery and radium together, used discreetly and discriminately, a great deal may be done, perhaps more than has been done, to alleviate the distressing disabilities of inoperable uterine cancer, and in many cases to restore to those suffering derelicts peace of mind, together with the chance of an increased term of economically useful life.

3. On the End Results of Colectomies for Chronic Intestinal Stasis.—A. W. Sheen presents the histories of three cases in which the war enforced a beneficial patience, in that "cures" were not claimed by immediate publication, and in which the term "end results," tautologically but well understood, is justified. In the three cases there was great improvement, which, in two, might be termed complete success. The qualifying details are: In the first case a ventral hernia with dyspeptic symptoms; in the second, adhesions, fortunately not interfering with pregnancy; in the third, diarrhea occasionally. A fourth patient died after the operation. Discussing briefly the toxic theory of stasis as expounded by Sir Arbuthnot Lane and his followers, the use of the belt and paraffin, the resort to colectomy, and the employment of alternative procedures, the writer states that it must be a commonplace with those, like himself, who have had a surgical experience of the abdomen extending over many years, that various operative measures have seemed to cure patients who, *inter alia*, had signs and symptoms of toxic stasis. He cites a case in point, and holds that such cases justify his contention that there are more surgical ways than one of curing toxic stasis, and that every case should be treated in accordance with the special indications it presents. Nor does he advocate surgery as the only remedy. Diet, drugs, aperients, paraffin, massage, exercises, posture, abdominal supports, regulation of life, change of climate, spa treatment, removal of toxic foci—all have their place in the treatment of intestinal stasis. In the treatment, operative and non-operative, the psychic factor must not be overlooked. The rest and careful after-treatment are of benefit after all abdominal operations. The prevention of stasis and toxic foci should begin in babyhood and continue. The earlier the treatment the better, and then the less severe and more potent it is. Prevention is the final goal.

6. The Drooping Shoulder Sign of Phthisis.—W. C. Rivers directs attention to a physical sign of phthisis not mentioned in any British text-book, which was present in half of the last fifty consumptives sent to him for diagnosis. On the affected side, or (generally) the side of the more extensive or older disease, the point of the shoulder and the nipple are lower than on the other side; the nipple is also smaller and seems to lie further back. Behind, the scapula is lower—its inferior angle may reach three inches below that of its fellow—and is at a different distance from the spine, mostly nearer to it. Muscular atrophy also is noticeable, a little of the pectorals, but far more of the upper part of the trapezius. The superior border of that muscle, instead of running straight from neck to shoulder, is flattened, wasted, hollowed out, so that, as compared with the opposite side, much less of it shows above the clavicle when viewed from the front, and above the spine of the scapula when viewed from behind. The sign occurs indifferently in men and women, although more marked in the former; and as regards association with the type of phthisis, in this order of descending frequency—juvenile hilus cases, a rather large proportion; third stage cases (Turban-Gerhardt),

very early half; first stage cases, nearly half; second stage cases, about a quarter. He has seen it develop in the course of a few weeks.

3. Benzyl Benzoate in Pediatric Practice.—John Ruräh became interested in this subject through the work of Macht, who found the drug useful in the inhibition of peristalsis and the relaxation of the spasm of smooth muscle. In infants and young children many distressing symptoms are caused by the great tendency to spasm of the smooth muscles, and he believes that consideration of the uses of benzyl benzoate in pediatric practice may be of service in stimulating study of this drug, which, it would seem, bids fair to become a permanent part of therapeutic armamentarium. In pediatrics it may be used in place of atropine wherever a relaxing effect is desired on spasm of smooth muscle. Ruräh has used it sufficiently to be able to recommend it in bronchial asthma, spasmodic bronchitis, gastric or intestinal colic, hiccup, and spasmodic constipation. It has been recommended by others in excessive peristalsis. In whooping cough its action is often most beneficial, but the results are uncertain, as is the case with all other antispasmodics in this disease. In general convulsive conditions not dependent on organic lesions of the central nervous system, especially in the newborn, the drug will be found of benefit. It is non-toxic, but not particularly agreeable to take.

5. Alimentary Hypersecretion; Gastric Hypersecretion; Gastrochronorrhea.—Crohn and Reiss make the observation that in the present period of clinical gastric research the attention of the majority of workers is focussed on diseases characterized by organic or structural changes in the tissue wall of the stomach and duodenum. The result is that the observations of functional disturbances have fallen into the background and a lesser interest and eagerness have been shown in attempting to reclassify and evaluate the various forms of secretory disturbances to which the stomach, as a major secreting organ, is subject. Because of the confusion associated with the phrase "gastric hypersecretion" the writers have collected the views of those who have previously been interested in this topic, which they summarize as follows: A. *Continuous Hypersecretion* (Magensaftfluss or Reichmann's disease), a malady having a characteristic clinical picture and evidenced by continuous outflow of large quantities of secretion in both the digestive and interdigestive and fasting states. Surgery has pretty nearly classified most of these as cases of pyloric stenosis due to ulcer: the medical men succeeded in establishing a smaller number on the basis of pure neurosis. B. *Continuous Hypersecretion*, occurring not chronically, but in intermittent form, associated with periodic migraine, tabetic crises, paroxysmal hysterical vomiting spells, etc. These are accepted by all as cases due to excessive stimulation of the gastric nerves of central nervous system origin. C. *Alimentary Hypersecretion*, not really a disease, but a symptom or chemical phenomenon occurring during digestion. This milder form of secretory stimulation was shown to be a very common phenomenon and generally attributed to protopathic

organic origin, usually ulcer. From their own studies the writers draw the following summary: 1. Hypersecretion is a symptom; it is a functional disturbance of the secretory apparatus of the stomach. It is not a disease *per se*. 2. It is a frequent symptom, occurring most commonly in males, and being present in probably at least 10 to 15 per cent. of all persons with gastric complaints. 3. Its occurrence is independent of the acidity titer of the stomach; it is found more often associated with hyperacidity, but can be seen through all the grades of acidity, even in achylia gastrica. 4. Most of the cases of hypersecretion are of the continuous type, lasting through the digestive and interdigestive period. The most severe type of cases, when associated with vomiting, emaciation, thirst, epigastric pain, etc., constitutes Reichmann's disease. These cases are nearly all due to gastric or duodenal ulcer (intrinsic cause). 5. Of the milder grades of continuous hypersecretion (alimentary hypersecretion, without vomiting, etc.), many of the cases are attributable to ulcer (about one-third); the remainder are due to abnormal nerve irritation, either reflexly from abdominal disease in other organs or from neurotic instability, such as vagotonia, psychoneurosis, etc. (extrinsic cause). 6. A few cases are due to diseases of the cerebral system, hysteria, psychic causes, etc. (intermittent hypersecretion). Under the head of treatment the writers direct attention to the importance of removing both extrinsic and intrinsic stimuli of an abnormal nature. Restriction of diet is one of the basic principles; rest in bed is a necessary corollary of this treatment. In a series of cases of hypersecretion previously reported the effect of marked restriction of diet, both solid and fluid, was studied; 45 per cent. showed local improvement in the chemism of the stomach and 80 per cent. were discharged from the hospital free of symptoms. The use of atropine is warranted by experiments. They were able to demonstrate a striking reduction in the supersecreted fluid after hypodermic administration of this alkaloid. Less favorable results followed the administration by the mouth or over longer periods. The removal of abnormal nerve stimuli, whether of cerebral nerve system or of viscerosensory origin, is self-evident; no treatment that ignores the psychical condition of the patient will be effectual in a case wherein vagotonia is a factor or hysteria or a psychoneurosis is present. Organic brain or spinal cord disease once diagnosed calls for its own treatment.

3. Thrombosis of the Coronary Arteries; A Clinical and Pathological Study.—James Edgar Paullin cites four cases of the condition under consideration. Death usually results in the pronounced cases, but he considers one justified in assuming that some can recover. Early diagnosis is of the greatest importance. Absolute rest in bed for days and weeks is necessary. The only hope for recovery lies in securing for the infarcted area as rapidly as possible an adequate supply of blood through its collateral circulation. The ability to do this depends on the condition of the unobstructed artery, the extent of the anastomosis and the size of the infarct. It has been shown by Miller and Matthews that the

death rate in dogs following ligation of the coronary artery is much lower where the animal receives digitalis or strophanthus, and that these drugs are useful in promoting and increasing the collateral circulation. May it not be assumed, then, that the same condition will obtain in man, and that by administering, intravenously or hypodermically, either strophanthus or digitalis, the heart is being helped to establish this collateral circulation? To be of value this remedy must be used early and in sufficient dosage to get a quick effect. The writer has seen no good result from the use of nitroglycerin or the nitrites. Morphine in sufficient dosage to relieve pain is absolutely necessary.

11. Some General Considerations Regarding Prostatectomy.—J. T. Geraghty gives the following indications for suprapubic prostatectomy: 1. When a suprapubic cystostomy has been recently performed for drainage, the enucleation usually should be carried out through the suprapubic opening. 2. A previous perineal operation or the presence of a dense scar about the bulbous or membranous urethra. 3. Multiple small calculi, especially when associated with diverticula. 4. Where prostatic hypertrophy is complicated with a lesion of the spinal cord the danger of incontinence following prostatectomy will be very considerably lessened by suprapubic removal. 5. Where there is present a very large intravesical hypertrophy with great dilatation of the internal sphincter, suprapubic prostatectomy will give better functional results. In this type of case, frequently following perineal prostatectomy, there is a slight weakness of the sphincters with consequent annoying dribbling, which may persist for some months. In the vast majority of these cases, however, the incontinence, which is only slight, disappears. Where no special indications exist for the perineal operation the suprapubic should be the method of choice. 6. Where it is impossible, because of ankylosis of the spine and hip, to put the patient in the proper perineal position. Some of the indications for perineal prostatectomy follow: 1. In every old and feeble man perineal prostatectomy seems preferable to the writer. This operation is attended with considerably less shock than the suprapubic operation, which inherently causes greater disturbances than the perineal. 2. Small fibrous prostates should be removed perineally, as successful removal through the suprapubic route may be very difficult or almost impossible. 3. Patients with a great deal of abdominal fat should be selected for the perineal operation rather than the suprapubic, because the fat does not resist infection well, and convalescence consequently may be protracted. 4. Where there is present a very large inguinal hernia the perineal operation seems definitely indicated. 5. Where there is present a localized area suspicious of carcinoma, better exposure of the involved part will be secured through the perineum, because cancer of the prostate nearly always occurs in the posterior lobe. In occasional cases it will be possible to excise completely the carcinoma without doing a complete radical operation. It is impossible, by the suprapubic route, to remove carcinoma involving the posterior lobe. 6. Repeated previous suprapubic operations are an indication for the opposite route.

3. Clinical Versus Laboratory Findings in Syphilis of the Nervous System.—C. S. Holbrook holds that there is no field in medicine where the importance of a correct and prompt diagnosis is more desirable than in syphilis of the nervous system, and that such a diagnosis frequently is not readily made. Syphilis, it has been said, may mimic any disease of the nervous system, and the typical syndromes described in text-books are seldom found, and are valuable only in the descriptive art. In

the study of a person with nervous or mental symptoms assistance should be sought from all sources. The family history, the personal history, and habits of the patient, together with the clinical findings, should be thoroughly scrutinized. When further information is desirable the laboratory should be called into requisition. Many of the more or less atypical cases of paresis, tabes, and meningitic luetic infections have been allowed to progress for months and years, not because these diseases were not considered, but because some laboratory tests proved negative. As a matter of fact, the blood Wassermann is of such little value in syphilis of the nervous system that a negative reaction should receive little consideration, and a positive reaction means that the disease may be due to syphilis or that it is present in a syphilitic. Usually in syphilis of the nervous system distinct changes in the spinal fluid will be found. There are four tests that are of value, the cell count, the globulin content, the colloidal gold test, and the Wassermann reaction. All of these tests should be made in each examination, for, not infrequently, it is found that one or two of the tests are negative while the others point to syphilis. Almost any combination of results may be present. In rare instances the blood and spinal fluid are negative to all tests and yet the patient is suffering from syphilis. When a patient gives rather vague symptoms, especially of the so-called neuroathetic type, and when a history of a venereal sore can be elicited, it is very important that syphilis be ruled out as far as possible by an examination of the spinal fluid. Any person showing Argyll-Robertson pupils should be considered as suffering from cerebrospinal syphilis until proved otherwise. Unequal, irregular, slowly reacting pupils, absent or unequal patella reflexes, should also place one on guard. The clinical findings should always be of primary importance and the laboratory ones of only secondary importance.

U. S. Public Health Reports.

February 11, 1921, xxxvi, 6.

Epidemic Encephalitis (Encephalitis Lethargica; Nona).—Dr. H. F. Smith, U. S. Public Health Service, after a careful review of the literature dealing with the epidemiology of encephalitis lethargica, reports on 153 cases occurring in the United States during 1918 and 1919. One hundred and five of these were in persons twenty years of age or over. The relation of the disease to influenza was studied. Since about 30 per cent. of the entire population had been infected with influenza during the pandemic, significance could attach to the occurrence of a previous history of influenza in cases of encephalitis only if this percentage was markedly exceeded. In the series studied 46 per cent. gave such a history. In the case of males this percentage rose to 71, while in females it dropped to 29. This difference is striking, since the incidence of influenza during the pandemic was approximately 30 per cent. for each of the sexes. The mortality from encephalitis lethargica was almost three times as great in cases with a sudden onset as among those in which the onset was gradual. Ptosis was observed in 95 per cent. of the cases, diplopia in 83 per cent., blurred vision in 72 per cent. Asthenia was present in 93 per cent. of the cases, and an acute debilitation out of all proportion to the temperature and relative severity of the other symptoms was one of the striking characteristics of the cases. Fever was the most constant of all symptoms. Examination of the spinal fluid was of value in excluding other conditions. No specific data were discovered on which a diagnosis of encephalitis lethargica could be made definitely, though many of the fluids showed positive evidence of a reaction of the meninges due to an inflammation of the brain tissue. Such evidence consisted in an increase in cells, or in protein substances, or both. In over half of the cases the white blood count was under 10,000. Blood culture done in four cases was negative. Animal inoculations, in monkeys, were negative, but the inoculated material was not fresh. Approximately 900 persons were exposed in the immediate families of the cases reported, and no secondary cases could be discovered. Case fatality rate was 29 per cent. for all cases, and 60 per cent. for cases with a sudden onset.

Book Reviews.

DIAGNOSTIK UND THERAPIE DER MAGENKRANKHEITEN, von Prof. Dr. T. BOAS, Berlin, 7te Auflage. Leipzig: Geo. Thieme, 1920.

THIS well known book of Boas has just appeared in its seventh edition. Of the many new items contained in the present work a few may be cursorily mentioned. Boas does not approve of administering alkalies in hyperchlorhydria at the height of digestion. This has a tendency rather to increase gastric secretion. Boas prefers to employ the alkalies one-half hour before meals. Aluminum silicate is recommended as one of the best remedies to combat high acidity; it is given in half to teaspoonful doses in water, half an hour before meals. In gastric hemorrhages Boas is a believer in strict rest, abstinence from food and drink and the administration of opiates. Everything is treated in the most practical way and the book may be warmly recommended to every practitioner of medicine who reads German.

THE RADIOGRAPHY OF THE CHEST, Vol. 1, **PULMONARY TUBERCULOSIS**. By WALKER OVEREND, M.A., M.D. (Oxon), B.Sc. (Lond.). Hon. Radiologist and Physician to the Electrotherapeutic Department, East Sussex Hospital (Hastings); Radiologist to the City of London Hospital for Diseases of the Chest (during the War); late Chief Assistant in the X-Ray Department, St. Bartholomew's Hospital; Physician to the Prince of Wales' Hospital, London, and Radcliffe Travelling Fellow. St. Louis: C. V. Mosby Company, 1920.

FOLLOWING a brief and too general reference to the technology involved, there are fully and ably discussed the normal structures that register on the x-ray plate, in the radiograph of the chest. Dr. Overend comments on the various classifications of pulmonary tuberculosis heretofore advanced and presents, for the purposes of radiography, a description of the following types: Tuberculous disease of the bronchial glands, disseminated nodular phthisis, disseminated nodal phthisis, bronchopneumonic pseudolobar tuberculosis, chronic attenuated phthisis, fibroid phthisis, pneumonic phthisis, miliary tuberculosis. Tuberculosis of the bronchial glands is again divided into mediastinal, hilar, and perihilar. Case histories and x-ray photographs reproduced are used to demonstrate the types. Bronchopneumonic phthisis is described as nodular, nodal, and pseudolobar,—according as the foci are quite small and nodular or large and multilobular. The pseudolobar type is almost exclusively unilateral as the result of hilar or perihilar glandular affection on the same side. In chronic attenuated or minor phthisis the radiographical manifestations are arranged as follows: (a) apical nodular, (b) apical infiltrative, (c) perihilar discrete and disseminated, (d) perihilar infiltrative, (e) perihilar fibrotic, (f) lymphatic disseminated, and (g) bronchitic. Illustrations and case histories of each example are presented. Pulmonary fibroid tuberculosis includes those cases in which the radiogram shows evident fibroid deposits, extensive areas of fibrosis, or evidence of considerable displacement in internal organs and deformities of the chest wall, with or without the presence of cavity. Miliary phthisis is next considered, together with its complications. Pneumothorax, emphysema, cavities, and bronchiectasis are considered as complications in tubercle. Finally, there is a chapter on the radiographical diagnosis of pulmonary tuberculosis in which clinical comments and illustrative cases appear. In the concluding remarks, Dr. Overend justly presents the inadvisability of expecting the radiologist to determine at one examination the diagnosis in cases which have possibly puzzled one or more skilled clinicians. Multiple examinations are recommended, supplemented by many plates, both plane and stereoscopic, more particularly of such areas as may be regarded with suspicion.

A TEXT-BOOK OF HISTOLOGY. By FREDERICK R. BAILEY, A.M., M.D. Sixth Revised Edition. New York: William Wood and Company, 1920.

THE fact that this text-book has reached its sixth edition is in itself proof that it has met with general approval. The present revision shows evidence of a careful inspection for the need of changes necessary to bring it up to date but no change in the general plan

of the work has been made. The chapter on the nervous system occupies about one-third of the volume and has been written by Oliver S. Strong. The new edition will probably increase the size of the already wide circle of friends possessed by this work.

DIE PARTIGENGESETZE UND IHRE ALLGEMEINGÜLTIGKEIT, Erkenntnisse, Ergebnisse, Erstrebnisse. Allgemeinverständlich, dargestellt von Hans Much, Universitätsprofessor in Hamburg, Leipzig: Curt Kabitzsch, 1921.

MUCH believes that all natural antigens are in fact antigen mixtures. The several constituents which he conceives go to make up this antigen mixture, he has designated as partial antigens or, as he has contracted the words, "partigens." This pamphlet is the presentation of the author's views of the laws governing the activities of the partigens. In each antigen mixture there are said to be four partigens: a water-soluble portion, albumin, lipid and fat. Since his whole argument is based upon the claim that lipoids and fats have antigenic properties as well as albumins and since this claim is vigorously protested by probably the majority of immunologists perhaps all that can be said is that the author's thesis is interesting if true. The pamphlet is purely a philosophical presentation of the question and contains no experimental evidence to support it. It makes interesting reading.

A NATURALIST ON LAKE VICTORIA, with an Account of Sleeping Sickness and the Tse-Tse Fly, by G. D. HALE CARPENTER, D.M., B.C.H. (Oxon), Uganda Medical Service. New York: E. P. Dutton & Co., N. D. (1920).

THIS is a delightful book. The author spent parts of four years in the vicinity, and on the islands of Victoria Nyanja, in a study of the bionomics of the Tse-tse fly, *Glossina palpalis*, under the auspices of the Royal Society. The book gives evidence of the closest and most painstaking observation and the knowledge gained of the habits of the fly is most extensive. Native "boys" were trained to collect the fly, and its relative abundance or rarity in a given place was determined by the average number of specimens taken "per boy per hour." The natural enemies of the fly are considered, and the possible means of eliminating it; although the author is not apparently sanguine of much success in this direction.

To the naturalist, and particularly to the entomologist, the book will prove especially interesting, since more than half its pages are devoted to descriptions of the mammals, reptiles, birds, fishes, and insects generally observed in the region. The style is simple and non-technical, although the chapter on "The Colouration of Insects" can hardly be so described. The book is most interesting and readable; the illustrations are numerous and especially fine.

WARFARE IN THE HUMAN BODY. By MORLEY ROBERTS, with an Introduction by Professor ARTHUR KEITH, M.D., F.R.C.S., F.R.S. London, Eveleigh Nash Co., Ltd.

THIS is a book by a keen student of man and nature. Most people know of Mr. Roberts as a novelist of note, they do not know of him as a keen sociologist or as no mean artist with the brush as well as the pen. In the volume he deals with the pathology of human societies as well as with that of the human bodies. And to do this he has studied in the laboratory as well as in the open in observing nature. When such points are dealt with as malignancy, inhibition, the theory of immunity, heredity and environment, the physiology of consciousness and the psychology of training, the reader is sure of a very wide field to traverse. But the assurance of Professor Keith is warranty that the subjects are handled in no quasi-scientific fashion but deeply and thoughtfully, whether one agree with the author or not. The fact is that the book is one abounding in suggestive thought and well repays reading and thinking over. Not the least of the points is that to deal with these problems the scientist of wide observation is needed of the calibre of Wallace or Darwin, in place of the specialist observer of to-day. One point the author has made is that bearing one another's burdens is a first rate plan of social life. This is heretical according to modern education, but it might prove efficacious according to the author in dealing with some of the worst forms of social inflections.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held January 24, 1921.

THE PRESIDENT, DR. GEORGE GRAY WARD, JR., IN THE CHAIR.

Inaugural Address of the President.—The Relation of the Medical Profession to the Community.—Dr. GEORGE GRAY WARD, JR., delivered this address. (See page 337.)

Severe Rachitic Involvements of the Thorax and Certain of Their Consequences.—Dr. EDWARDS A. PARK of Johns Hopkins Hospital, Baltimore, read this paper, which was liberally illustrated with lantern slides. He stated that in the course of severe and prolonged rickets the thorax was invariably affected and often became the seat of most extensive deformity. The milder degrees of rachitic involvement were in themselves of little or no importance. The more severe involvements, however, might after a time become a veritable menace to life itself. In examining the chest of a child suffering from what we might most properly call rachitic osteomalacia of the thorax one was at once struck by the peculiarities of the deformities and the behavior of the deformed thorax in respiration. In the first place the chest was small, measuring from 9 to 12 cm. less in circumference than the head at a time when the thorax should be as large as the head. In the second place it was shaped very roughly like a wedge, the anterior part of the chest corresponding to the narrow end of the wedge. Its unusual shape was due to depression present at both sides in the region of the costochondral junctions and extending backward and forward so as to narrow the thorax anteriorly. In the expiratory position these depressions extended from the midaxillary line to within two or three centimeters of the sternum in front and from the fourth rib above to the ninth rib below. The deepest points were found at the sixth and seventh costochondral junctions and here the depression might be a centimeter or more in depth. It was in most instances greater on the right than on the left side, apparently because the heart acted to protect the left side. Indeed on the left side there might be no depression. With inspiration the deformities were much increased. The depressions became widened and deepened. They extended from within two centimeters of the sternal margin to the posterior axillary line and from the second rib to the tenth rib below, where the thorax began to flare out over the abdomen. The floor of the depression sank with inspiration backward and inward toward the vertebral column. Owing to the collapse of the sides of the thorax during inspiration the circumference of the chest at the level of the nipples remained the same during inspiration and expiration, or might be actually diminished by a few millimeters during inspiration. Thoracic respiration alone considered must therefore result in an actual inspiratory loss of intrathoracic space. *This must in itself bring severe respiratory disturbance.* These deformities were brought about because the bony thorax had lost its rigidity as the result of the failure of calcium deposition and calcium withdrawal consequent upon rickets. There was also a weakening at the costochondral junctions brought about by the rachitic process in the so-called metaphysis or intermediary zone. The chief factors operative to produce deformity were the pull of the diaphragm and atmospheric pressure. Atmospheric pressure caused the ribs to sink in at their weakest parts anteriorly, the pull of the diaphragm bent the ribs and their cartilages inward, and both of these factors caused the cartilage to be displaced upon the rib through the rachitic zone, so that instead of forming a continuous line, the cartilage was attached to the rib obliquely or even at right angles. Such changes in the thoracic wall eventually brought about changes in the thoracic contents. When the thorax was opened knuckle-like enlargements were found projecting into the cavity of the thorax, and grooves, one on the external surface of each lung not far from the anterior border, ran in a direction from above downward, somewhat outward and backward.

When the lungs were pulled forward into their anatomical position, the grooves on the surface of the lung came to lie directly opposite the line of the deformed costochondral junctions, and the depressions in the grooves exactly corresponded to the costochondral prominences. This groove divided the surface of the lung in such a way that roughly one-quarter lay in front of it and three-quarters behind. The part of the lung in front of the groove was mostly emphysematous, that behind the groove was generally largely atelectatic. The changes in the heart consisted principally in dilatation and hypertrophy of the right ventricle. The columnæ carneæ were thick and flattened out against the ventricular wall. The weight of the heart was increased out of proportion to the body weight. The heart was usually heavier than the liver, kidney, or spleen, as compared to the body weight. The liver occupied an extremely low position which was explained by the correspondingly low position of the diaphragm. The intestines were usually distended. Dr. Park described the physical signs and clinical picture presented by an advanced case of rickets, and stated that the clinical picture suggested pneumonia and had usually been considered in that light, yet it was noteworthy that the temperature was rarely greatly elevated; it was usually low, and not infrequently normal. The leucocyte count was usually low. In 30 cases studied with that point in mind, it varied between 4,000 and 15,000 and averaged 11,000. The clinical picture was caused by the loss of rigidity of the respiratory bellows, the result of the rickets, with continued collapse of the thorax and loss of its power to expand. The atelectasis increased. As a result of the atelectasis the pressure on the pulmonary circulation rose, hypertrophy of the right heart followed, later perhaps of the whole heart. If the rigidity of the ribs became still further impaired, a point was reached at which the disabled respiratory machine was just sufficient to maintain itself under normal conditions. When now a slight additional burden was put upon it in the form of an infection, it became insufficient to perform the work demanded. Nature then resorted to the only expedient possible—respiration became enormously increased. The course of such cases was subject to great variation; some became progressively worse until death intervened; in others an alternating exacerbation and decline of symptoms might continue for weeks. If these children did not die they might gradually improve, and, given time, osteoid tissue might be produced in such quantity as to give the shafts of the rib and the costochondral junctions the requisite rigidity. It was most important to realize that deformity and normal thoracic function were entirely compatible; that the element of danger was not deformity but the loss of rigidity of the thorax. With the aid of cod liver oil calcium salt could be made to deposit in the rachitic metaphysis and the shaft and a true healing of the defect brought about by the rachitis be accomplished. With the aid of cod liver oil the thorax could be made to become rigid or nearly so in about two months. In spite of the cod liver oil treatment the deformities would persist months and perhaps years. Gradually, however, the deformities of the thorax were outgrown. Rickets was often looked upon as a disease not in itself threatening to life. It did threaten life, however, when situated in the thorax even without added infection. Treatment should chiefly be directed toward prophylaxis. Such extreme rachitic affections as had been described must never be allowed to develop. At present the only treatment for these acutely sick cases which they were able to advocate from their experience was the administration of cod liver oil, preferably in small doses, the avoidance of those things which gave rise to the abdominal distention, and the best care.

The Treatment of Rickets. Especially the Results Accomplished by Means of Cod Liver Oil.—Lantern Slide Demonstration.—Dr. JOHN HOWLAND of Johns Hopkins Hospital, Baltimore, gave this presentation. He stated that there was hardly a disease like rickets that was so old and yet so new, that was accurately known clinically centuries ago and that interested pediatricians and experimenters intensely at the present time. Yet with all the efforts that had been expended, particularly in the last ten years, we were without a clear understanding of the cause of rickets.

A good deal had been done, much had been learned, and the direction that investigation would take was reasonably plain. It became increasingly evident that food played the essential if not the whole rôle in the process. It had been hard to reconcile certain facts with this conception, for instance, that infants developed rickets of the most extreme grade when being nursed by their mothers, and that they did it also when receiving cows' milk, and that they became rachitic far more frequently at certain times of the year, notably the winter and early spring. But other facts compelled the conclusion with even greater insistence that food was the essential factor. Animals could be made rachitic with complete regularity when an improper diet was given to them; they could be cured by a proper diet, all other influences remaining the same. The proof of these facts with rats left nothing to be desired. At some future and probably not distant date the one who wrote upon the treatment of rickets would speak in terms of food factors and food composition. Now in the beginning of our knowledge we were not in so favorable a position. With little doubt it would be possible to give directions for making the milk of nursing mothers or of healthy cows antirachitic in its influence. But at present we were marking time and waiting for further information. So far as diet was concerned we must still give infants and young children food which we knew contained the essential factors for nutrition in a proper amount and in such form that it was capable of being digested, which was no more than we tried to do with all children. We could in many instances place children in good hygienic surroundings, but this would not necessarily cure rickets; it might help somewhat. And so we had used remedies, and very many had been advised and used, and only two had had much reputation. These were cod liver oil and phosphorus. Cod liver oil had been used to a considerable extent for only the last fifty or sixty years. It had been advised for many different conditions, especially for tuberculosis and in children for almost every known disease and lately especially for rickets. It could truthfully be said that it had been regarded by some as a specific and by others only as an easily assimilable fat. There were metabolism studies first by Schabad and later by Ernst, Schloss, and others to show that calcium was retained better in rickets when cod liver oil was given, and there had been clinical studies by Hess and Unger to indicate that cod liver oil would prevent the development of rickets. What he wished to present now was ocular evidence that cod liver oil would cure rickets and the most severe rickets. Dr. Howland then showed slides and described the conditions due to lack of calcium. Other slides showed ossification centers and the gradual deposit of calcium following the administration of cod-liver oil. As the result of their studies, of which the pictures shown represented only a small part, it seemed to him that most of us had been very blind, and he confessed that he had been among the blind. We had a specific for rickets and we had not appreciated it. The reason for this was that cod liver oil was not immediate in its effects or at least its effects were not immediately evident. Cure might be going on and we could not appreciate it. Deformities did not become less, they rather were more apparent for a time. Enlarged costochondral junctions were firmer and more readily felt. Thoracic deformities were not improved; enlarged epiphyseal extremities did not at once subside. But the disease in the bones was brought to a standstill and was cured and after a number of weeks the bones were firm. Very gradually unnecessary enlargements disappeared as did the callus after a fracture and many minor deformities became less. With so potent a preventive as this it was imperative to see that the deformities never arose. It took a long time to cure rickets. The evidences of improvement often did not show for four to six weeks, or perhaps more, but they became progressively more marked and the end result was nearly certain. It seemed sufficiently evident then that in the empirical remedy cod liver oil we had a specific and that we could therefore wait with equanimity the day when more exact knowledge would enable us largely if not entirely to prevent this deforming, economically important, and probably eradicable disease.

Dr. ALFRED F. HESS said he thought all would agree

that it was very difficult to discuss these papers as the demonstration was so complete and convincing. As Dr. Howland had said, there had been a particular interest evinced the last five or ten years in rickets. This was partly due to the general interest in nutritional disease and also in part to the great increase in rickets in the Central Empires where, as was well known, rickets had assumed almost epidemic form in Germany, Austria, and other countries. The one practical therapeutic advance was our realization of the value of cod liver oil. Dr. Hess said he had been interested in this matter and with Dr. Unger, in 1917, had carried out a study in one of the negro districts of the city, Columbus Hill. Here they selected a number of infants and children and gave them cod liver oil both as a therapeutic and as a prophylactic measure, doing this in the winter and spring when rickets was most frequent. It was quite remarkable how the rickets was cured; in over 80 per cent. of the cases there was a definite clinical cure. As Dr. Howland had said, we were able to prevent and to eradicate it. In this city there were about 65,000 children between three and fifteen months of age (the age at which rickets occurred); if, say one-third were unable to buy cod liver oil it could be furnished to that number of children for \$150,000 a year. In other words, by the expenditure of \$150,000 a year we could practically eliminate the disease. Following the progress of rickets by the x-ray was also a great advance of recent years. It would enable us to separate the remedies that had value from those which had no value. As was known there were many advertisements of preparations which were said to be just as good as cod liver oil. Many of these were said to contain a small amount of cod liver oil and were used by physicians and the laity in place of cod liver oil. We could now test such preparations and prevent their false labeling and their use instead of cod liver oil in this disease. In this same district a study was carried out by Dr. Unger and the speaker as to the diet of the negro mother and, without going into details, it might be said that there was one prominent characteristic, namely, they took little fruits and fresh vegetables and an excess of carbohydrates. A similar study carried out last spring and fall showed the same lack of fresh vegetables and fruit.

Dr. OSCAR M. SCHLOSS said he could well agree with Dr. Hess as to the difficulty of discussing these papers. They furnished a very clear cut demonstration about which there was relatively little to be said. The thing that had impressed him during the last few years was the extreme frequency, not only among the type in which we usually saw extreme grades of rickets, but also among the better classes. If we assumed that head sweats and small enlargements of the costochondral junctions were evidence of rickets, then a very large number of infants suffered from moderate grades of this disease. Another interesting point was the extreme variability of the symptoms, the symptoms being more pronounced in one direction in one patient and in another direction in another patient. Dr. Schloss stated that he had recently seen three children who developed green-stick fractures from slight injuries. These were children whom he had seen as infants and they had all shown evidences of rickets. The x-ray plates at the time of fracture showed rather decided rickets, and the tendency to fracture cleared up after administration of cod liver oil. Another condition not identical with rickets but perhaps related to it in which cod liver oil was useful was so-called congenital soft skull, though it was not always congenital, as it sometimes developed during the course of two or three months. It was surprising the way in which these almost totally membranous skulls would ossify under the administration of cod liver oil. The first one of these cases he saw some years ago and that patient had demonstrated that cod liver oil was really as useful as it had been demonstrated to be this evening. Within a few weeks the skull was quite hard, and it had seemed almost impossible that it could have been the result of the medication. The repeated experience of such results lent assurance to the belief that this was cause and effect. Dr. Schloss stated that he believed the natural conclusion was that the use of cod liver oil should be spread rather widely, not only to Italians and Negroes who developed ex-

treme grades of rickets, but it might be well to spread this knowledge to the better classes in which slight or moderate grades of rickets often developed.

Dr. WALTER LESTER CARR said it was impossible to overestimate the value of the papers of the evening. All one could do was to endorse and learn from what had been said. Dr. Park spoke of the deformities of the chest with bone changes in rickets and the associated lessening of thoracic expansion. It always seemed to him that the atmospheric pressure of fifteen pounds to the square inch not only caused a lessening of respiratory activity but also impaired the circulation as the amount of inspired air was diminished, and this interfered with the venous return from the respiratory and intestinal tracts. As a result a catarrhal condition was established. These children were therefore highly susceptible to infection and it was recognized that it was difficult to care for a bronchopneumonia in a case of rickets. The catarrh of the intestinal tract interfered with digestion and absorption. The reason there were so many preparations of cod liver oil on the market was because physicians had not understood the dosage for cod liver oil and were led to use other less valuable oils. Sometimes children could take only moderate doses, and if there was a great deal of mucus in the intestinal tract the oil might not be emulsified. These were matters of clinical observation. He felt that all should bear the reproach that more attention should be paid to the use of cod liver oil in the treatment of rickets.

Dr. WILLIAM P. NORTHRUP said he hoped a retired teacher would be pardoned for taking pride in the fact that these two pupils of his were the star performers of the evening. Dr. Howland he had examined for the Presbyterian Hospital and had lived with him at the Foundling Hospital. Dr. Park also was at the Foundling Hospital with him. These pictures that Dr. Park showed looked like old friends. He had seen all these queer twisted bones at the autopsies performed at the Foundling Hospital. One found every kind of twist and deformity, so there was nothing to add to the scientific discussion except to express his appreciation of the fact that they had found a cure for rickets. The diagnosis of rickets was easy, the prognosis was the experience of all, but when it came to a specific that was really adding something. He thought they all felt very grateful to both speakers.

Dr. ROWLAND G. FREEMAN said it was a pleasure, when so many of our old remedies were turned down, to come back to cod liver oil and get a scientific demonstration of its efficiency. He was sure all present felt very grateful to the speakers.

THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting Held December 22, 1920.

THE PRESIDENT, DR. HERMAN B. ALLYN, IN THE CHAIR.

Intravenous Citrate of Soda Treatment of Thromboangiitis Obliterans (Berger's Disease).—Dr. WILLIAM A. STEEL of Philadelphia presented this paper and said that thromboangiitis obliterans affected all the coats of both arteries and veins, and begun usually in the legs below the bifurcation of the popliteal and from there spread into other vessels. In this country it was almost entirely limited to middle-aged, male Russian Jews. The symptoms were due to the gradual shutting off of the arterial blood by the occluding thrombus. The first sign was pain in the foot or calf while walking or standing, usually attributed to rheumatism or flatfoot, relieved on sitting down and holding up the leg but recurring on further attempts at walking. The affected foot became purple when dependent and blanched when held horizontal; it felt colder than its fellow and was sensitive to cold, damp weather. The author had employed sodium citrate method of treatment for the past three years, with encouraging results, by the following technique: during the first month the patient was kept in bed with the legs constantly in either a hot air or electric light bath at 110° F., and 250 c.c. of 2 per cent. sodium citrate solution were given intravenously every second day. During the second month the interval of injection was lengthened to every

third or fourth day, daily leg massage was given and the patient put in a wheeled chair with feet hanging down for a short time each day; or, if the case was not advanced, some walking was allowed. The intervals of injection were then gradually lengthened until at the end of a year one was given every two weeks. Increased walking was permitted as the symptoms subsided. Potassium iodide in 10 grain doses 3 times daily was given during the whole course of treatment. Six cases had been treated; 2 had resumed their regular occupations; one was walking with good function; one, with a previous leg amputation, had resumed his occupation as a playwright; one very desperate case walked after one year of treatment, relapsed at 4 months and was now yielding to a second course of injections; the sixth case was progressing satisfactorily.

Dr. J. CHALMER DACOSTA of Philadelphia said that he was very much interested in this subject and believed that Dr. Steel had given us the only plan of treatment that had really proved of service. He did not think it could be stated as emphatically as had formerly been done that all the cases were in Hebrews, because he had personally seen 3 cases which had occurred in persons not Hebrews and born in Philadelphia. He did not think that we should allow the absence of Hebrew blood to influence us in the diagnosis in these cases. Early diagnosis before the onset of gangrene was of the utmost importance. Women were free from this malady. The absence of pulse was not constant. It was apt to be absent during the attack of pain and to return on relief of pain. Intermittent claudication varied in severity from merely a nervous symptom to crippling pain. The bright red color was characteristic. He thought that the condition characterized by this bright red color was what Weir Mitchell called erythromelalgia. The future of these cases was ominous. The disease was inexorable.

Dr. MOSES BEHREND of Philadelphia said that in the Jewish Hospital with which he was connected they got these patients quite often and he was compelled to say that his experience with the sodium citrate treatment had not been so favorable as Dr. Steel's; they had used gallons of it. When one leg had been amputated it was not a very pleasant prospect to the patient to contemplate amputation of the other leg. In such cases they had given sodium citrate a very thorough trial. One such case in the Mt. Sinai Hospital had been treated very thoroughly, but finally the second leg had to be amputated. Sodium citrate doubtless relieved the pain but it did not cure the condition.

Dr. W. WAYNE BABCOCK of Philadelphia said that the rule had been with some surgeons to amputate early and high in order to save the patient the discomfort of a progressive disease. Dr. Steel had not had to amputate in any case he had seen. He thought that we could feel that Dr. Steel's method of treatment was worthy of a great deal of our praise and enthusiasm. He thought that in any case which came to us we were in duty bound to carry out this treatment with thoroughness and care.

A Simple Method of Administering Tuberculin That Has Proved Efficacious.—Dr. MYER SOLIS-COHEN of Philadelphia read this paper in which he said that the appropriate initial dose of tuberculin for the individual patient was that amount which, when injected intracutaneously, gave the minimal reaction as indicated by induration. If this dose was followed by favorable reaction, such as amelioration of the symptoms, a feeling of well being, rise in spirit, increase of appetite, reduction of temperature, it was repeated as these good effects were passing off until it no longer was followed by improvement, whereupon it was increased by 50 per cent. increment until it again produced a favorable reaction. If the initial or any subsequent dose failed to have any influence, it was likewise increased until it produced a favorable reaction. Any dose that was followed by an unfavorable reaction, such as rise of temperature, exacerbation of the symptoms, malaise, anorexia, pain, loss of weight, was reduced from one half to one thousandth, depending upon the severity of the reaction. Old tuberculin (O. T.) and tuberculin Rückstand (T. R.) administered in this way to patients in the incipient or moderately advanced stage with temperature below 100° who had not been improved sufficiently would injure none and improve many. In view

of the wide variation in tuberculin hypersensitiveness, which in two patients of apparently the same type might vary one million times, any method of administering tuberculin that gave practically the same initial dose to every patient was dangerous even in so-called expert hands. Tuberculin was merely one of many therapeutic measures of value in tuberculosis. It was an important adjuvant to and not a substitute for the necessary physiological and medicinal treatment.

DR. JOSEPH TURNER of Eaglesville, Pa., said that the early disfavor in which tuberculin was held following Koch's discovery could be attributed to the fact that it was not known how to use it and also that tuberculosis was really a mixed infection. In recent years it had come into more favor among those who were working in tuberculosis, and chief among those had been Trudeau. In the past tuberculin had been given in too big doses. He had given tuberculin to 39 adults and 1 child without selecting the cases. Some of them got an arrest of the disease and were able to go home and go to work. Some did not get well. Those who did get well were, with one exception, the type that are getting well this year without tuberculin. Out of 40 cases he could think of only one who might have been benefited by tuberculin and he was not sure of that. He did not think that tuberculin was a specific for tuberculosis. If it were there would not be about 50 or 60 varieties of it.

DR. A. E. ROUSSEL of Philadelphia said that his experience with tuberculin had been restricted to about a dozen cases in adults in the Eaglesville Sanitarium. The results obtained in this series had been very much the same as those mentioned by the last speaker. He had not observed any improvement in any of these cases and he was quite satisfied that in two of them there had been an increase in symptoms.

DR. W. WAYNE BABCOCK of Philadelphia said that in some of the cases of tuberculous glands and sinuses he had observed a marvelous improvement. He had seen many old discharging tuberculous sinuses which, after a single dose of tuberculin had stopped running as if a spigot had been turned off. He had had a few cases in which enlarged glands of the neck were reduced in a week or ten days after a single large dose. Such results were obtained in about 10 per cent. of the cases. The doses in all these surgical cases had been from 5 to 10 mgm. He had tried the injection of tuberculin directly into the gland in children and found that it had caused a rapid liquefaction and healing.

DR. HERBERT FOX of Philadelphia said that he thought that all that could be gained by the use of tuberculin was to raise the tolerance of the individual for the toxin. There were no clinical or laboratory evidences that immunity had been produced. He thought that Dr. Cohen's ingenious application of the skin test as a control of the amount with which to start this toxin resistance was a very nice point.

DR. MYER SOLIS COHEN said that he felt that tuberculin was still on trial. Most incipient cases did well without tuberculin. He would not think of giving tuberculin to a patient who was doing well on ordinary measures. He did not believe in comparing groups one of which was getting tuberculin and the other was not. Among those who were getting tuberculin there were some who were getting too much and it was doing them harm; whereas some of them who were not getting it would have been benefited had they received it. There was no doubt that in some cases tuberculin did good and in others harm.

Color Vision.—This paper was read by Dr. C. P. WEBER of Washington, D. C., who said that the seat of color vision diagnosis was found in the iris. Besides being a curtain which shielded the retina the iris was also a shield against invading color. When the eye was forced to observe a certain color for a long time, the iris changed its color to suit that of the invading impression. It required several years for this change to take place. The iris took on the color which was complementary to the color which it was forced to observe. The entire spectrum was represented in the color of the iris, beginning with red at the center and concluding with violet at the periphery. When the change of color took place, the color disappeared in the corresponding concentric ring. In the condition known as color blindness the iris appeared a pale, dull yellow bordering slightly on a greenish tint. This condition

was produced principally by work under artificial light. It would also be produced by the amethyst lenses which were popular a few years ago, if worn long enough. A careful study of the subject of color vision had resulted in the production of a cure not alone for color blindness, but for all conditions arising from the false use of color. The main object in the procedure of a cure was the change of the color of the iris. When a cure was to be made, a choice must first be made as to which of the normal conditions is the right one for the patient at hand. The time which the iris required for a change with the proper glasses ranged between two and four months. Headaches which arose from the false use of colors were relieved almost instantly by the selection of properly colored lenses.

Polyorphism of Epidemic Encephalitis (Lethargic); The Types of the Disease and the Differential Diagnosis.—Dr. Alfred Gordon of Philadelphia read this paper in which he said that the clinical picture of lethargic encephalitis presented great variety. The literature abounded in examples of its polymorphous character. In view of its polymorphism errors of diagnosis were likely to be made. The general characteristics of the malady consisted of three principal symptoms: fever, ocular palsies and somnolence. The somnolence might present various degrees from slight drowsiness with a tendency to sleep on sitting down to the deepest unconsciousness. Palsy of the ocular muscles was a common symptom. It was usually an early manifestation. The most frequent symptom was ptosis which was in the majority of cases bilateral. The internal muscles of the eyes were less frequently involved. Inequality of the pupils, mydriasis and nyosis, paralysis of accommodation, mild strabismus were the conditions observed. Various motor and psychic manifestations were met with. The following types might be observed: Myoclonic, choreic, hemiplegic, convulsive, meningeal, Parkinsonian, bulbar, neuralgic and neuritic, mental, cerebellar, poliomyelitic, sensorial, paraplegic, and incomplete. The disease must be differentiated from polioencephalitis, cerebral abscess, anterior poliomyelitis, cerebral syphilis, intoxications, narcolepsy, coma, and stupor. Lethargic encephalitis was a protean disease with its histological characteristics of a definite type, but with a great variety of localizations throughout the entire central nervous system.

DR. CHARLES K. MILLS of Philadelphia said that he thought the facts were in a nutshell that there were peculiar pathological lesions widely focalized. Perhaps the most difficult thing to understand was why in so many cases we had the triad of symptoms to which he had referred. It was less difficult to comprehend its protean forms if we considered what we knew of its pathology. He had studied and written about, together with one of his colleagues, what we know as cerebellar and the cerebellobulbar type of this disease. The paralysis agitans type was very much like that described many years ago as pseudoparalysis agitans and was probably given this characteristic by the focalization of the lesion in the lenticular nucleus. It seemed to him the triad of symptoms was due to some peculiar selective action of the infection on certain parts of the nervous system. Everyone of us who had had experience with the disease had been impressed with this characteristic.

DR. J. HENDRIE LLOYD of Philadelphia said the name sleeping-sickness should never have been applied to this disease. It was well named encephalitis. One of the most important differential points was that of syphilis. We all know that abnormal somnolence was common in cerebral syphilis. Dementia præcox, where the symptoms were cataleptoid, might simulate this disease. This was also true of hysteria.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 16, 1920.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

The program of the evening was arranged by the Committee on Library.

The Deeds and Needs of the Library of the Academy.—DR. GEORGE DAVID STEWART made a brief address in which he pictured the way in which books enabled us

to go back through the centuries and live with other men in other times. In his library a man could dwell at the court of kings or with the Olympian gods. Books were the heritage left us by those whose experiences had brought them something of truth, or usefulness or beauty which they wished to share with the rest of humanity. If one wished to be not a mere spectator in the world's drama he wrote a book, or he became an actor and performed some deed that another embalmed in writing, for books were powerful and enduring. Towers had fallen, walled cities had crumbled to earth and temples had moulded to dust, and their glory had vanished and would be forgotten were it not for books. Dr. Stewart said that books were dynamic, and exerted a great force and influence in our lives. A well chosen library was the greatest preventive of presenility. Speaking more particularly, of the Library of the Academy, he said that it was one of the largest medical libraries in America, ranking next in size to that of the Surgeon General. Its popularity extended all over the United States and Canada. The first query of almost every man applying for membership in the Academy was "How soon may I use the Library in the afternoons?" Recognizing this demand, they permitted applicants for membership to pay a fee and become library subscribers during the time they were on the waiting list. Space was urgently needed. The readers had increased almost 4,000 during the past year, to be exact, from 23,500 in 1919 to 27,457 in 1920. In the effort to get more space they were constantly making rearrangement. Old shelves from the council room, removed to make way for new fireproof cases for the classics, had been placed along the walls of the hall above the Library. This with the room formerly occupied by the Public Health Committee gave a little additional space and permitted some of their books to leave unworthy positions on the floor and climb to their rightful places among the irresistible aristocracy on the shelves. It was true that some of their members had left generous legacies, the income from which was sufficient this year to pay library expenses amounting to nearly \$20,000. But this was a very modest sum and not nearly enough. They should and must expand. It should be possible to admit medical students at all times of the day. The fact that the curricula of medical schools permitted, and medical students sought admission to the Library was strong evidence that medical education was covering a broader field. At present, however, the admission of medical students was impossible; there was neither the space nor the necessary staff of assistants. There was another class of readers in the Library, a small and silent band that Osler said was the leaven that leavened the whole lump. Voltaire once made the unfortunate remark that rare books were worth nothing, since if they were worth anything they would not be rare. We knew better nowadays. We knew that in some old books there was much that might appeal to the few but to them with the voice of a clarion. There were books that had lain silent for a century and then had spoken with the trumpet of prophecy. As Thoreau said, "Two thousand summers had imparted to the monuments of Grecian literature, as to her marbles, only a maturer, golden and autumnal tint, for they had carried their own serene and celestial atmosphere into all lands to protect them against the corrosion of time." Recognizing the needs of this small band and also that a knowledge of medical history might and did prevent old errors from again becoming current, the Library Committee recently asked the trustees for a small allowance wherewith to purchase some of these rare old books, and a modest amount was voted. Then through their Librarian, who presented the case with skill a friend appeared who fulfilled the prophecy of the test, "Ask and it shall be given," for he not only donated the books but the case in which they were displayed and protected. Alexander of Macedon carried with him on his expeditions a copy of the Iliad, possibly the only one then extant, in a precious casket. They were not in a position at present to indulge extensively in rare books, since it was with difficulty that they supplied the necessary modern volumes. However, they invited the members of the Academy to look at the precious casket that had been provided in which their Iliad would be protected and preserved when they brought it to join the company of immortals. For their scientific necessities they needed a great deal

more. When such large sums were given for all sorts of educational and medical endeavor, it seemed incredible that the New York Academy of Medicine could not and did not receive enough to provide for its legitimate and wholly altruistic activities. Surely it was because their character and need were not known.

The Story of a Great Consultation in the Sixteenth Century—Jerome Cardan Goes to Edinburgh.—Dr. CHARLES L. DANA made this contribution, in which he described the trip of Jerome Cardan, then Professor of Medicine at Paris, to Edinburgh where he had been called in consultation by John Hamilton of Edinburgh, Archbishop of St. Andrews, who was in a distressful state of mind and body. He was 40 years of age and for ten years had suffered from asthma. He had advised with his personal physician and had consulted the royal physicians at the Courts of Francis I and Charles V of Spain. He was told that his disease was due to a moist brain, a distillation of phlegm accumulated in that organ and discharging itself through the windpipe into the lungs, causing cough, expectoration, and dyspnea. Dr. Dana related that Cardan was at this time 50 years of age and in very poor health. After forty years of hardship, antagonism, and miscellaneous diseases he had "arrived." He had a distinguished clientele, and had been called to be physician to the Pope. He had declined this honor and had just resigned his University position. He was free to travel when Dr. William Cassinate, the Archbishop's personal doctor, sent him a letter some ten thousand words long begging him to go to Lyons and possibly to Paris where he could see and examine the Archbishop. Cassinate sent him 200 crowns and he started for Lyons with five attendants. Upon arriving at Lyons, after a three weeks' trip, Cardan found neither the Archbishop nor his doctor there. He was, however, kept busy for thirty-eight days with entertainments and consultations, at the end of which time Dr. Cassinate arrived with a letter from the Archbishop, explaining that he was too ill and too busy to leave Edinburgh. Would not Cardan come to him? He sent him 300 crowns for his expenses, promised him 10 crowns a day for his trouble besides many honors, presents, and a "great harvest of fame and esteem." Cardan did not want to go, for he thought England immensely cold; that the grass was full of worms, and the sky darkened with crows. However, he finally accepted the commission and started for Paris on April 18. He was entertained by the royal physician, asked to be physician to the King, and to give his services to various nobles of the day. He met in consultation the famous Jacobus Sylvius, teacher of Vesalius. Cardan described him as a "merry old man of 70, quite bald, quite little, and full of jokes." The other consultant was Fernal, Professor of Medicine in the University, and a most important figure in Medical History. They had a dinner party and discussed the case of the Archbishop from a clinical and Galenic point of view. Their theory was the "moist brain" above alluded to. Cardan listened, kept silent, and ventured no opinion. He here made his final arrangement with the Archbishop's physician. A contract was drawn up and then destroyed as being an instrument unnecessary between a physician and an honorable patient—an interesting commentary on the medical ethics of the day. Cardan and Cassinate traveled down the Seine to Rouen, with the former's five attendants, and part of the way with an escort of fourteen horse and fifteen foot soldiers, for France and Spain were then at war and Cardan was a subject of Charles V. They went to Boulogne, then to Calais, and thence to London, arriving on June 3, 1552. Here they stayed three days and then started for Scotland, arriving twenty-three days later. Cardan stayed in Edinburgh until September 12, a period of ten and one-half weeks. For forty days after his arrival Cardan did not begin his treatment. Being a prudent man he allowed the Archbishop's physician to carry out again the treatment that had been approved by the Paris consultants, Sylvius and Fernal. But the Archbishop got worse and finally Cardan explained his position. The Archbishop was very much annoyed at the delay and told Cardan to apply at once his theory of the disease. Now Cardan thought that the Archbishop's brain, instead of being cold and humid, was hot and dry (perhaps we would not say hyperemic). This caused humors distilled in the stomach to rise to the brain. Also materials in his food were

turned into phlegm, which passed into the bronchial tubes, causing cough, expectoration, and dyspnea. As a matter of fact, the Bishop was a great eater and drinker, and took no exercise; he worked hard; kept irregular hours; was not shy with the ladies. Practically Cardan put him on a Wier Mitchell rest cure. This was about as follows: He rose at eight and took a shower bath—the first taken in Scotland. He then took a walk in a shady place, chewing a little mastic, the 16th Century substitute for pepsin gum. This caused expectoration and helped purge the brain. At 9 o'clock he had breakfast, consisting of liver, with a little ginger and some bread, and two ounces of white wine. After breakfast he rested and amused himself. From 12 to 4 he was allowed to attend to his business, but was forbidden to write letters with his own hand. At 4 he went for an hour's ride on horseback. Then, sitting or reclining, he was allowed to give audience to those who wished to see him. He had supper at 7 o'clock which was like breakfast, but opened with the 16th century cocktail, consisting of a teaspoonful of pure honey. He was to go to bed at half past eight and secure ten hours of continuous sleep. As specialties in the diet, he was recommended turtle soup, snails, barley water, and chicken broth. The Archbishop accepted the advice and medication prescribed and promised that he would report at the end of two years. Cardan had the follow-up system in his practice. In two years the Archbishop did write to say that he was nearly well. The chief object of Cardan's cure by medicine was to reduce the temperature of the brain. To do this, the head must be purged and before that there was to be a purgation of the body. The head was purged in those days through the palate, the nose, and the sutures of the skull. So Cardan blistered the coronal suture and poured a mixture of milk and water with two grains of elaterium through the nose, this being done on an empty stomach. Cardan did not believe in blood-letting nor in much medicine, and these were about the only medications that the patient received; but the attention to hygiene and diet was very strict and definite. He limited the amount and character of his food, kept him away from the hot sun, forbade him to sleep on a feather bed, and made him use a linen pillow. He gave him as a laxative preserved peaches and sugar of violets, and avoided purgatives. He made him drink a quart of milk a day. He was told to rub his head vigorously with an ivory comb and to give his extremities a vigorous rubbing every morning. He allowed him only two meals a day, and as a fattening agent gave him two ounces of sugar water dissolved in the broth of a young pig. He gave him cold natured food which would resist the attraction of the hot brain. Before Cardan left his patient, he prepared and wrote out his "Consilium Medicale" in which he gave his theory of the disease and provided for every detail of the treatment. This made a document twenty folio pages long. It was probable that the Archbishop asked for something simpler, so Cardan wrote a shorter outline of seven pages folio. Cardan left Edinburgh in September and spent some weeks as the guest of the Court of Edward VI, a youth of 15 years. Dr. Dana quoted from the account of a conversation between Cardan and Edward VI and commented upon it showing that Cardan thought the young prince the prodigy of learning and cleverness he was assumed to be.

Dr. Dana then reviewed the impressions of England and her people that Cardan carried away with him. He returned home by way of Belgium, Holland, and the Rhine, spending several days with Frisous at Louvain, and visiting other notable men of the time, among them Conrad Gesner, who was a physician, a botanist, a zoologist, and one of the most industrious and learned men of all time. He published in twenty volumes a catalogue of all the writers who had ever lived. Cardan finally reached his home in Milan, on January 3, 1553, having been gone 310 days. He wrote an autobiography "De Vita Propria," which was quite short, very objective, unsparing in its self-analysis, and full of curious details of his own personality and career. It has been called one of the three great autobiographies in literature; the others being Caesar's "Annals" and Rousseau's "Confessions." Cardan was sensitive, affectionate, introspective, imaginative, superstitious, humorous, in-

clined to ideas of self-reproach, with high ambition and hypomanic industry. Concerning his weaknesses, he admitted he was always inclined to sensuous pleasures. Of these he added his worst and greatest was love of music. He got very melancholy over this defect in his morals. Cardan represented the learned men of his century. His writings were a mirror of what was best in the art, practice, learning, and ethics of the day. In his art he was not behind later centuries. In his ethics he was abreast even of those of today.

Medical History a Safeguard Against Medical Fads.—Dr. JAMES J. WALSH made this contribution, in which he declared that undoubtedly the most important chapter in the history of medicine was that of the cures that had failed. Every generation of physicians of which we had any definite records had had high confidence in a series of remedies which seemed to them, for the time at least, to be curative of some of the rather serious symptoms, if not actually the serious diseases of mankind. Further experience with these remedies had shown that they were without good effect or were of most trivial significance, and often indeed time served to show that they were distinctly harmful rather than helpful. This course of events had been repeated over and over again. Probably nothing would do more good for medicine than if we could secure some remedy for this disease of running after fads to which physicians were so susceptible. Not all of them did the patients harm directly, but some of them did, and all of them did harm indirectly by wasting time with useless remedies. Personally, Dr. Walsh said, he had the feeling that the only remedy for this unfortunate tendency was to be found in a reasonable knowledge of the history of medicine. Properly studied that was just full of the stories of fads and also of warnings in regard to them. A good many people would feel that the cures that failed were a thing of the past because we had reached such a firm foundation of scientific medicine for our therapeutic ideas that we were not disillusioned in the way our fathers were, and our remedies endured. There was a very definite tendency to think that in nearly everything in our generation we were very far ahead of the past and in nothing more than in the critical ability to discriminate the apparent from the real, and enthusiastic claims from realities, but that was only a nice bit of self-complacency that each generation had had its turn. We pitied the generations of the past that they did not live to see our glorious time, but in our turn we should in future be pitied just as complacently. As a matter of fact there probably never was a time when men were so easily led to accept exaggerated claims of any and all kinds as at the present time. The recent experience with Ponzi in Boston was an excellent illustration of that. Anyone who thought that we had become less susceptible to suggestion in this generation must be hiding himself from the realities of present day life. Our popular education and our newspapers and magazines, with their advertising pages reeking with suggestion, had as a matter of fact made us ever so much more suggestible than ever before. It was surprising then to find that physicians shared at least somewhat in this suggestibility of the generation and adopted conclusions occasionally that proved to be not well founded. There were a number of reasons why the medical profession in our time came to adopt remedies that afterwards proved to be of little or no service to our patients. We had ever so much more research than in the past and many of those who pursued medical investigations had the feeling that they must justify their work by making announcements from time to time. As a result not a little of our medical research was not carried out to its legitimate conclusions before it was announced to the public. Besides we were blest, dubiously enough, with a large number of manufacturing pharmacists whose business it was to get hold of what seemed to be novel ideas in therapeutics and exploit them. The commercializing of therapeutics had added greatly to the number of cures that had failed and we had had remedy after remedy highly advertised, popular for a while, and then dropping back into the limbo of disused drugs or discarded modes of treatment. To illustrate this Dr. Walsh reviewed our experience with so-called cures for tuberculosis and cancer. During the same quarter of

a century that we had had this large number of remedies for the cure of tuberculosis and cancer, we had also had such movements as the use of organic extracts of various kinds and then the vaccines, for so many of which the medical garret was yawning at the present time, and then the various modes of treatment connected with the theory of focal infection carried to its uttermost extreme. Then we had a series of remedies coming and going dependent on the theory of intestinal autointoxication as the cause of nearly everything under the sun in medicine, and a few other things besides, an example of those alluring glittering generalities of theory which prove so tempting to physicians all down the ages. Since Pasteur's great discoveries the feeling that there must be antiseptics that would cure microbial disease had been the source of a great many different kinds of remedies. We had forgotten that all down the centuries the idea of killing disease whenever pursued to any serious extent had nearly always led to the killing of the patient or at least to his serious injury before his disease was affected as unfavorably as we had hoped it would be through the use of antiseptic materials. The history of medicine represented the one possibility of giving men a background for judgment, critical and safeguarding, with regard to new remedies. The history of medicine taught that important discoveries had been made in every generation and gave the physician an open mind for medical progress. This always came from observation, not theory. The history of medicine was a monitor with regard to the pursuit of elaborate theories and their tendency to lead even those who had the best of good will in the world and a good deal of knowledge far afield in the pursuit of will 'o' the wisp that invariably led us out over the swamps and quicksands of disappointment from which it was not easy to return to the hard narrow path of real advance. The history of medicine as regards surgery was full of suggestion for modern development and was also valuable as a background for the judgment of such fads and fashions as judging of character by the shape of the head or by physical stigmata, or treating insanity by drastic measures, whether medical or surgical, and even helped us to understand such waves of popular interest as hypnotism, spiritism, and the like, so constantly recurring in the history of humanity. Dr. Walsh then went on to show some of the absurdities of drastic purgation and venesection, remedies of the nineteenth century that had failed, and mentioned some of the remedies for epilepsy and insanity that had gone into the discard. A few years ago there was a definite proneness to think of at least certain forms of criminality as representing insanity and operations on the brain were suggested for them as a cure. In one very well known case here in New York an habitual criminal actually succeeded in having himself operated on for the relief of pressure supposed to be due to an old injury, and then, after having had the reputation of being the worst criminal anywhere in the United States, was for two years a model prisoner so that at last pardon was obtained for him and a great deal of commiseration was expressed for the "poor fellow" who had spent so much time in prison as a criminal, though he was only an unfortunate sufferer from brainstorms which took the direction of acquisitiveness as regards others' property. He had been scarcely two years out of the penitentiary before he turned up as the head of an organized band of burglars, and the experiment in the cure of supposed moral insanity became merely a subject of ridicule. It was interesting to realize as a commentary on this that some of the very oldest skulls we had, from the New Stone Age, bore marks of having been trephined, with such healing after the operation as evidently indicated that the patient must have recovered completely, at least from the operation. They called it letting the bad spirits out that had gotten into the man. Were we not doing exactly the thing when we yielded to the sentimental considerations of theorists and set about relieving our criminals in the same way. Not that we should not make observations, but that the medical history of such cases ought to warn us not to draw hasty conclusions from our observations, but to wait until the significance of the observations had become clear. Dr. Walsh then recalled Dr. Phineas Quimby's

success in the cure of psychoneuroses and the continuance of his success by Mrs. Eddy and pointed out the analogy of their methods to those of Freud. He said he was aware that the followers of each of these modes of therapeutics, Eddysm and Freudism, would indignantly repudiate all question of their having any possible relationship to each other and would proceed to emphasize the fact that they had very special theories of religion and psychology and it was not the theories but the facts that made their successful therapeutics an absolute demonstration. He recommended both of them to Oliver Wendell Holmes essay on "Hahnenanism and Kindred Delusions" to emphasize the rule that facts were not truths unless you had all the facts and that cures as facts were the most delusory thing in the world. The history of the applications of psychology to medicine were full of analogies to Freudism. The idea that Freud had revolutionized psychology was founded on utter ignorance of the older psychology and the history of philosophy generally. What was new in the Freudian doctrine was not true, and what was old in it was often utterly misconceived, but it had caught on just as so many other delusions. The psychoneuroses had had a wonderful lot of cures proclaimed for them. We could understand these better since our experience in the past generation with hypnotism. It would be remembered how hypnotism cured a number of the psychoneuroses until it seemed that we had a great new adjunct for therapeutics. And now the definition of hypnotism that was growing in favor among neurologists and psychologists was that it was induced hysteria. Hysteria was simply supersuggestibility. We cured one form of unfavorable suggestion by producing another, but then long ago Hippocrates said that one pain might drive out another. Curing hysteria by hypnotism, or curing a psychoneurosis by inducing hypnotism often left the state of that person worse than before, as the profession had found; and we now knew that experiences with hypnotism could be traced back in the centuries. The therapeutics of hysteria and the psychoneuroses was dangerous ground. It was extremely thin ice that one had to skate over and history erected a danger signal that everyone ought to see. Dr. Walsh then went on to speak of character analysis, of which we had heard so much in the last few years, and of the recognition of special talents and the selection of men for certain jobs and positions by the external appearance of their heads. Literally hundreds of thousands of dollars had been spent in advertising a system of directions as to how this was to be accomplished, and where money was spent in advertising the outgo would not be continued for any length of time, as in this case it was, unless the sales far more than exceeded. Evidently a great many people had been taken in by the new pseudo-science, the abandoned pseudo-science of phrenology come back again, and hard headed business concerns had paid out actual money in large quantities to "experts" and so-called professors of psychology to tell them all about the men they were to employ from the external appearances of their heads. At the present time we had more panaceas for success in life and remedies for failures, taken right out of psychology than at any other time in the world's history. Psychology was a magical word to conjure with. Of course it was the new psychology. The main thing that was new about was its power to extract representatives of the precious metals from the pockets of mankind. "The one hope of reasonable limitation of the proclivity to be fooled, for there is considerably more than one of them born every minute, is to know about our forefathers, not how they killed each other and let rotten diplomacy disturb them and king's mistresses use them as toys (that is not history, those are the kitchen scandals of humanity), but how men lived and worked and were fooled and how they got out of it in all times just as in our own."

Herelle's Phenomenon.—According to Salimbeni, if one filters through the Chamberland filter the intestinal contents of a dysenteric subject very small spores pass through. These if subjected to culture efforts germinate and develop into myxamebæ. The zymase secreted by this organism can dissolve the Shiga bacillus.—*Gazette des Hôpitaux*.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

MEDICAL COUNCIL OF CANADA.

Toronto, Winnipeg, and Vancouver, June, 1920.

HYGIENE AND STATE MEDICINE.

1. What factors are accountable for the closeness experienced in the air of an ill-ventilated room? Discuss the general effects on health of living in poorly ventilated quarters, and at the same time outline some tests for efficiency in ventilation in school rooms.
2. Discuss possibilities of milk as a carrier of disease, and what steps would you take to prevent this?
3. Given full authority, discuss the individual and public measures you would employ to check the further spread of (a) epidemic meningitis, (b) typhoid fever, (c) diphtheria.
4. What do you understand by "personal hygiene," and what rôle does it play in the field of preventive medicine?
5. What diseases of animals may be transmitted to man through meat or milk, and what preventive measures would you use? Also state how you would recognize these diseases in meat.
6. What diseases are most commonly water borne? Discuss measures to be taken by a community to prevent water carrying infection.

PATHOLOGY AND BACTERIOLOGY.

1. What microorganisms are commonly found in the spinal fluid in acute cerebrospinal meningitis? Describe fully the organism responsible for the epidemic type of the disease.
2. Discuss aortic aneurysm, illustrating the course of its development by detailed reference to gross microscopic findings.
3. Describe in detail the blood picture of splenomyelogenous leukemia. Give the differential diagnosis.
4. Write a brief descriptive paragraph on the morbid anatomy of insular sclerosis.
5. Describe the gross and microscopic appearances of carcinoma of the body of the uterus. How does it differ from that of the cervix uteri? How does it spread?
6. Describe, step by step, your method for determining the presence of streptococci in the blood stream. Describe the microscopic appearances in the case of a serous membrane, the site of streptococcus infection.

ANSWERS.

HYGIENE AND STATE MEDICINE.

1. *Factors accountable for the closeness in the air of ill-ventilated rooms:*—Physical changes in the air such as increase in the temperature and moisture, and lack of movement of the air; the giving off into the air of various organic matters from the bodies of the occupants of the room, these organic substances may come from the mouth, skin, lungs, teeth or clothing, and they cause a disagreeable odor; reduction of the oxygen; and increase of the carbon dioxide.

General effects on health of poor ventilation:—Headache, nausea, vomiting, vertigo, collapse, anemia, general debility, indigestion, lowered vitality, increased liability to various infections and to common colds.

Efficiency in the ventilation may be tested by:—Estimating the amount of air entering and leaving by the inlets and outlets, and the rate of its flow (this may be determined by an anemometer properly placed in the inlets and outlets); the air may be tested for the amount of carbon dioxide which it contains; the evidences of the senses is of value, the presence of stuffiness being particularly noticeable on coming in from the fresh air outside.

Pettenkofer's method of determining the percentage of carbon dioxide in the air:—A large cylindrical container of known capacity, say, 15 liters, is filled with the air to be examined; a known volume of barium hydroxide is then added and shaken up with the air. The carbon dioxide combines with the barium hydroxide to form a barium carbonate, which is insoluble, and also incapable of acting upon an indicator. The barium

hydroxide employed is of known strength, e.g. it may be of such strength that 1 c.c. of the solution neutralizes 1 c.c. of carbon dioxide at normal temperature and pressure. If then we find that 10 c.c. of the barium hydroxide has been neutralized by the carbon dioxide present in the air, we know that 10 c.c. of carbon dioxide is present in 15 liters or 15,000 c.c. of the air examined.

2. The milk may come from a diseased cow; it may become contaminated by the milker, the container, the surroundings, the water used to wash the cans or to adulterate the milk; or it may become contaminated at the dealer's or purchaser's house by being left uncovered, exposed to flies, etc., or by not being kept in a cool place. The only way to prevent the transmission of disease by milk is to insist on a thorough inspection of all dairies and sources of milk supply, and to educate the public in the care of milk between the time of its purchase and its consumption. The inspection should include: the color, reaction, specific gravity, sediment, taste, odor, acidity, total quantity of solids and of water; the percentage of cream, fats, lactose, casein, and ash; the presence or absence of preservatives, coloring matter, added solids, dilution, pathogenic micro-organism, dirt, or other foreign matter. There should also be thorough investigation as to its source, the cows and their environment, the method employed in caring for, milking, storing, and transporting the milk.

Diseases specially liable to be conveyed by milk: Tuberculosis, typhoid fever, scarlet fever, diphtheria, tonsillitis, cholera, and gastrointestinal disorders.

Essentials for the production and preservation of pure dairy milk: Vaughan's rules are as follows: "(1) The cows should be healthy, and the milk of any animal which seems indisposed should not be mixed with that from the healthy animals. (2) Cows must not be fed upon swill or the refuse from breweries or glucose factories, or upon any other fermented food. (3) Milch cows must not be allowed to drink from stagnant pools, but must have access to fresh, pure water. (4) The pasture must be freed from noxious weeds, and the barn and yard must be kept clean. (5) The udders should be washed and then wiped dry before each milking. (6) The milk must be at once thoroughly cooled. This is best done in the summer by placing the milk can in a tank of cold water or ice water, the water being of the same depth as the milk in the can. It would be well if the water in the tank could be kept flowing, and this will be necessary unless ice water is used. The tank should be thoroughly cleaned each day to prevent bad odors. The can should remain uncovered during the cooling, and the milk should be gently stirred. The temperature should be reduced to 60° F., or lower, within an hour. The can should remain in cold water till ready for delivery. (7) Milk should be delivered, during the summer, in refrigerated cans or in bottles about which ice is packed during transportation. (8) When received by the consumer it must be kept in a clean place, and at a temperature some degrees below 60° F."

3. *TO CHECK THE SPREAD OF EPIDEMIC MENINGITIS.*
"Individual measures:—(1) Recognition of the disease by its clinical symptoms, confirmed by the microscopic and bacteriological examination of the spinal fluid and by bacteriological examination of nasal and pharyngeal secretions. (2) Isolation of infected persons and carriers until the nasopharynx is free from infecting organisms, or, at the earliest until one week after the fever has subsided. (3) Immunization may prove of value, although the use of vaccines for immunization is still in the experimental stage. (4) Concurrent disinfection of discharges from the nose and mouth and of articles soiled therewith. (5) Terminal disinfection by cleansing. *General measures* are extremely difficult to carry out effectively; these consist of:—(1) Search for carriers among families and associates of recognized cases by bacteriological examination of the posterior nares of all contacts. Only a thoroughly trained technician can be trusted to isolate the meningococcus, and even such a one will frequently miss them when they are few in number. Cultures from the nasopharynx are most liable to reveal them. (2) Education of the public as to personal cleanliness, washing of the body daily and of the hands in soap and water before eating, keeping hands and unclean articles away from mouth, nose, etc., avoiding the use of common or un-

clean eating, drinking, or toilet articles of any kind, avoiding direct exposure to the spray from the nose and mouths of people who cough or sneeze, etc., and the necessity of avoiding contact infection. (3) Prevention of overcrowding, such as is common in living quarters, transportation conveyances, working places, and places of public assembly in the civilian population, and in inadequately ventilated barracks, camps, and ships among military units" (From Park's *Public Health and Hygiene*).

TO CHECK THE SPREAD OF TYPHOID FEVER. *Individual measures:*—(1) Early recognition of the disease by its clinical symptoms, confirmed by specific tests, the Widal reaction, and bacteriological examination of the blood, feces, or urine. (2) Isolation in a fly-proof room. (3) Immunization or preventive inoculation of all susceptibles who are known to have been exposed, or are suspected of having been exposed to the infection. This immunization is only relative and in no way does away with the need of precautions to prevent infection through water, milk, hands, etc. (4) Concurrent disinfection of all bowel and bladder discharges and articles soiled with them. (5) A general disinfection and cleansing of the room and its contents should be carried out at the termination of the case. *General measures:*—(1) Purification of public water supplies. (2) Pasteurization of public milk supplies. (3) Supervision of other food supplies and food handlers. (4) Prevention of fly-breeding. (5) Sanitary disposal of human excreta. (6) Extension of immunization by vaccination as far as practicable. (7) Supervision of typhoid carriers and their exclusion from the handling of foods. (8) Systematic examination of fecal specimens from those who have been in contact with recognized cases to detect carriers. (9) Exclusion of suspected milk supplies pending discovery of the person or other cause of contamination of the milk. (10) Exclusion of water supply, if contaminated, until adequately treated with hypochlorite or other efficient disinfectant, or unless all water used for toilet, cooking and drinking purposes is boiled before use." (From Park's *Public Health and Hygiene*).

TO CHECK THE SPREAD OF DIPHTHERIA. *Individual measures:*—Early recognition of the case, with isolation, and instruction as to care and disposal of excretions from nose and throat; early administration of antitoxin. *General measures:*—Administration of immunizing doses of antitoxin to all persons exposed to the infection after their susceptibility has been demonstrated by the Schick test; a search for carriers, and isolation and treatment of them when found.

4. By *personal hygiene* is understood the hygiene of the individual (rather than that of the public). It includes such matters as personal cleanliness, clothing, food, exercise, rest, the avoidance of excesses, care of the body in general. It plays an important role in the field of preventive medicine, because neglect of the matters referred to predisposes to many diseases and at the same time lessens the power of resistance to disease. Cleanliness disposes of many microorganisms; proper diet eliminates many bodily disorders which arise from excesses as well as from disturbed metabolism; care of the teeth and tonsils would eliminate many focal infections; attention to such matters as fresh air, and ventilation would obviate many headaches, and other troubles mentioned in *Question 1*: neglect of the eyes is the cause of much trouble;

5. *Diseases of animals which may be transmitted to man through meat* are:—Trichinosis, tape worm, echinococcus, tuberculosis, anthrax, septicemia, pyemia, tetanus, actinomycosis, foot and mouth disease, glanders. *Milk may convey:*—Tuberculosis, typhoid, scarlet fever, diphtheria, tonsillitis, cholera ad gastrointestinal disorders.

Preventive measures should include adequate inspection and supervision of the milk, as described in *Question 2*. For meat, there should be an adequate inspection of the cattle before they are killed, and an examination of the carcasses and internal organs.

Characters of good meat: "Meat when good and fresh should have a marbled appearance, due to streaks of fat between the bundles of muscle fibers. The color should be bright and not too dark, and the surface of the meat should be glossy and not dull. Beef is always darker than mutton, veal, or pork—chiefly for the rea-

son that sheep, calves, and pigs are bled more freely than oxen at the time of killing. The older the animal, the darker and tougher is the flesh. The connective tissue should be glistening and firm. The diaphragm should be firm, and the abdominal and thoracic parietes should show no evidence of adhesions or standing. The pleura should be intact. The bone-marrow should be set and be light red; the spleen, kidneys, and liver should be regular, of a good red, and without variations in color. Good meat is firm and elastic, and does not pit or crackle on pressure. It is juicy, but not wet; and the juice which adheres to the fingers should be of a bright red color. The fat is hard and dry, but feels greasy. The kidneys, spleen, and liver are firm. All lymphatic glands should be firm. The smell of sound meat is well known and characteristic. In order to test this more efficiently the meat should be pierced with a clean knife or skewer in the direction of the bone, and the implement smelt immediately upon its withdrawal. Good meat gives an acid reaction with litmus paper. Good meat, when dried upon a water bath, does not lose more than 75 per cent. by weight."

Characters of bad meat: "Meat that is bad is often soft and watery, some parts are harder than others, and there may be emphysematous crackling. The fat may be liquid or soft, highly colored or even hemorrhagic. A deep dark purple color is seen in meat when the animal has died without being bled, or when some pulmonary congestion or acute septicemia has affected the animal. The lymphatic glands in bad meat may be enlarged, congested, hemorrhagic, caseating, or calcified. The pleura, peritoneum, or viscera may show evidence of disease such as tuberculosis. Pus may be present between the muscle fibers. The carcass may show signs of emaciation. The odor may be that of putrefaction, and the meat may be alkaline in reaction. In advanced putrefaction the meat may become a greenish tint." (Pakes and Nankivell's *Science of Hygiene*.)

6. *Water-borne diseases*, are: Typhoid fever, cholera, dysentery, and some gastro-intestinal disorders.

The community should insist on proper municipal control of the water supply, including protection of the water-shed, and storing and delivery of the water, together with filtration and such chemical purification as may be necessary.

PATHOLOGY AND BACTERIOLOGY.

1. *Microorganisms found in the spinal fluid in acute cerebrospinal meningitis:* Micrococcus intracellularis meningitidis, pneumococcus, tubercle bacillus, staphylococcus pyogenes aureus, streptococcus pyogenes, bacillus of influenza, typhoid bacillus, and colon bacillus.

Epidemic cerebrospinal meningitis is due to the Micrococcus intracellularis meningitidis, which is a biscuit-shaped microorganism, generally united in pairs; it stains by the ordinary aniline dyes, and is decolorized by Gram's solution; it can be cultivated on a neutral glucose ascitic agar; it is claimed that there are four types of this microorganism; it is not motile and does not form spores.

2. *Aortic aneurysm:* "In saccular aneurysm of the aorta it is found that the sac most commonly springs from the convexity of the arch, and that intense arteriosclerotic alterations of the aorta surround its mouth. The orifice is round or irregular in outline, and the edge is rolled over into it somewhat, so as to almost overhang its cavity. The cavity itself may reach a very great size, the sac thus formed pushing aside the surrounding organs or embedding itself in them. Mechanical effects produced in this way are of great variety, depending largely upon the point of origin and size of the sac. Pressure on the recurrent laryngeal nerve produces an alteration of the voice from spasm or paralysis of the vocal cord, coughing, dyspnea, etc. Pressure on the trachea flattens it and causes dyspnea—later the aneurysm may rupture into it, after eroding its wall. The lungs yield and collapse before the aneurysm. Pressure on a bronchus narrows it, and behind the obstruction bronchiectasis arises. When the sac reaches the bony structures of the thorax, which do not yield, it hammers its way through them, appearing under the skin through a hole in the ribs or sternum. If it extends backward to the spine, it destroys the centre of the vertebrae even down to the spinal canal, leaving the yielding intervertebral discs

standing almost unaltered—in the same way it may break through the ribs in the back and appear under the skin there. Then it is not long before the skin becomes thinned out and bluish, and finally the sac ruptures, so that death follows at once. Often it ruptures long before it reaches the skin—into the pleura or pericardium, trachea, or esophagus, or even into the superior or inferior vena cava. . . . The sac is not composed of the stretched-out walls of the vessel, for microscopic examination shows that practically all those elements stop sharply at the edge of the orifice. The elastic tissue and the muscle are suddenly interrupted. Endothelium may persist and attempt to line the sac, but it soon fails in this and is lost. Indeed, nothing but connective tissue, and that essentially new formed, goes to make up the sac. It grows largely by new breaks in the wall which seem to be made good by further formation of fibrous tissue. The current of blood eddies about in the cavity, and its pulsation gives the sac its power of breaking down the resistance of the tissues. But the endothelial lining is imperfect, and thrombosis occurs, and if time be allowed, layer after layer of compact thrombus material may be hammered down on the wall of the sac until it is in large part filled up. Occasionally the aneurysm may be completely obliterated in this way. The character of the fibrous wall is such that little upgrowth of organizing granulation tissue into the thrombus appears, and the lower layers become even more compact, until, on a smoothly cut section, they look like onyx. The wall itself becomes hyaline, and it is often impossible to say, in a microscopic section, where the wall ends and the thrombus begins. In the smaller and fresher aneurysmal sacs the wall, wrinkled and irregular, is generally shining, thick, and rather translucent, and quite uncovered with thrombi or covered with only the merest film." (*MacCallum's Text-Book of Pathology*).

3. In *myelogenous leucemia*, the blood shows a permanent increase in the leucocytes other than the polymorphonuclear variety; myelocytes are present in great numbers, constituting from 20 to 60 per cent. of all leucocytes. The total number is about 300,000 per cubic millimeter as an average, but counts as high as 750,000 have been reported. The number, however, may be as low as 100,000 or even in some the count may approximate the normal. The differential count of the white cells in combination with the usual increase in number is the characteristic feature. The main form is the large mononuclear myelocyte containing neutrophilic granules. They may constitute some 35 per cent. of all the leucocytes. The nucleus is situated, as a rule, in the center and is well staining, it may be eccentric, however, or poorly staining. The large cell with the pale nucleus is seldom found in any other condition than in this form of leucemia. The neutrophilic granules may be lacking entirely and the nuclei show hydropic degeneration. Occasionally small myelocytes with deeply staining nuclei may be present. Eosinophilic myelocytes may be found in large numbers, varying from 3,000 to 100,000 per cubic millimeter. Such an increase is pathognomonic of splenomyelogenous leucemia. The ordinary type of eosinophiles is also increased. Basophiles or mast-cells are increased, sometimes very markedly, this condition being quite characteristic of leucemia. Polymorphonuclear neutrophilic leucocytes are relatively diminished as the myelocytes increase, and form about 46 per cent. of the total. They are absolutely increased to 60,000 or 70,000. Degenerative changes are very common, the cells becoming more cohesive, the nuclei pale and showing karyolysis or rhexis and frequently mitotic figures. Lymphocytes are not very numerous as a rule; they constitute about 10 per cent., although the number may vary considerably. The blood itself may be pale and the specific gravity lowered. Coagulation takes place slowly. The erythrocytes are decreased to about 3,000,000, the hemoglobin is diminished also, 40 per cent., color index about 0.6. Many of them are nucleated and show changes in size and shape. The normoblasts are very common, and megaloblasts are frequently seen. (*McConnel's Pathology*).

Differential diagnosis: In *leucocytosis*, there is only a moderate increase in the number of leucocytes, mainly in the polymorphs; and there are no myelocytes. In *lymphatic leukemia*, there is a marked leucocytosis, but

the increase is mainly in the lymphocytes; there are no myelocytes. In *Hodgkin's disease* there is no leucocytosis.

4. *Morbid anatomy of insular sclerosis*: "Grayish nodules are found distributed through the brain and spinal cord. They vary in size from a millimeter to two or three centimeters in diameter (one twenty-fifth to one inch). They are of firmer consistence than is the surrounding brain substance, but are not quite so hard as is ordinary connective tissue. They consist microscopically of neuroglia tissue, which some assert to be connected with the walls of the blood-vessels, as a rule. Very often the axis-cylinders of nerves can be seen passing through the lesion. The nodules are found most frequently in the white matter of the brain, more especially in the pons, internal capsule, and centrum ovale. They rarely begin primarily in the gray matter, but may invade it secondarily. The roots of the peripheral, especially of the cranial, nerves occasionally contain or are surrounded by these sclerotic masses. In the spinal cord they may extend up and down the gray and white matter for a considerable distance, or they may involve the whole cord at a certain level, turning it into a fibrous mass. The blood-vessels surrounding and in connection with these diseased areas show some evidences of thickening and increased vascularity, but no true inflammatory process, as a rule. The primary pathological change in multiple sclerosis is as yet unknown; many things point to its starting originally from small emboli or thrombi which lead to minute softening, with a secondary reparative and sclerotic process. The fact that the disease follows infective fevers makes such an origin of it seem probable. On the other hand, pathological anatomy does not yet bear out this view, and it is possible that the disease begins by a primary degeneration affecting first the myelin sheaths of the nerve-fibers sparing the axis-cylinders and cell bodies, this being followed by a neuroglia and connective-tissue proliferation which ends in the formation of the small islands of sclerosis. An important pathological peculiarity of the process is that, while it destroys the myelin sheaths of the nerves, the axis-cylinders remain intact for a long time and consequently conduction of nerve impulses takes place imperfectly, directly through the nodular masses." (*Dana's Text Book of Nervous Diseases*).

5. *Carcinoma of the body of the uterus*: "The uterus is generally enlarged, but it may be met with in a small senile uterus. Usually the general shape of the uterus is preserved unless the growth has extended deeply into the uterine wall. It is practically certain that the cancer originates in the endometrium, from the surface epithelium, or from the glands. The growth may be in the form of large nodular masses which project inwards towards the uterine cavity or infiltrate the wall externally. When the tumor projects markedly into the cavity, the uterine wall, as a rule, is not extensively infiltrated. The entire inner surface of the uterus may be involved, but usually the spread does not extend into the cervical canal. Instead of being composed of nodules, the neoplasm may consist of villous masses, which originate from the entire surface of the endometrium. These villous processes may be small or large, and they may be sufficiently numerous to fill the cavity. Diffuse corporeal cancer may, therefore, be met with in a nodular or villous form; but the former is the commoner. Sometimes the cancer is limited to the region of the fundus. . . . The typical appearance is columnar celled carcinoma, of which two main varieties may be found, one in which the irregular tubules that make their way into the walls of the uterus are regularly one cell thick, and the other where the lumen is encroached upon or filled up by many layers of cells. In the former case the malignancy might be considered as affecting the tubules as a whole, and in the latter as affecting the constituent cells also. Of course, both types may be present, with every gradation between them. The growth originates in the endometrial glands.

"*Spread of the disease in cancer of the body*: This is conducted by lymphatic channels in the broad ligament, higher up than those concerned in cervical cancer. These channels go to the lateral aortic lymphatic glands in the lumbar region, but very frequently in this case the interiliac glands are first affected, because

there is a very rich anastomosis between the two sets of lymphatics in the broad ligament. The disease may extend outward to the peritoneal covering of the uterus, so that adhesions form round the organ, and in many advanced cases pus collects in the cavity." (Cameron's *Gynecology*).

6. *To isolate the microorganism in the blood in a case of streptococcus septicemia.*—"The blood is taken from the median basilic vein. The skin over the vein should be prepared with green soap, alcohol, and bichloride of mercury, as for a surgical operation. The syringe should be of some sterilizable variety which is easily manipulated and does not draw with a jerky, irregular motion. Its capacity should be at least 10 c.c. It may be sterilized by boiling for half an hour. Before drawing the blood, a linen bandage is wound tightly about the upper arm of the patient in order to cause the veins to stand out prominently. When the veins are plainly in view, the needle may be plunged through the skin into the vein in a direction parallel to the vessel and in the direction of the blood-stream. After perforation of the skin, while the needle is groping for the vein, gentle suction may be exerted with the piston. Great care should be exercised, however, that the piston is not allowed to slip back and air be, by accident, forced into the vessel. In most cases no suction is necessary, the pressure of the blood being sufficient to push up the piston. After the blood has been drawn it should be immediately transferred to the proper media (glucose-meat-infusion agar and glucose-meat-infusion broth). At least six glucose-agar tubes should be melted and immersed in water at 45° C. Before the blood is mixed with the medium, the agar should be cooled to 41° C. in order that bacteria, if present, may not be injured by the heat. The blood is added to the tubes in varying quantities, ranging from 0.25 to 1 c.c. each, in order that different degrees of concentration may be obtained. Mixing is accomplished by the usual dipping and rotary motion, the formation of air bubbles being thus avoided. The mouth of each test tube should be passed through the flame before pouring the contents into the plates. Three flasks of glucose broth, containing 100 to 150 c.c. of fluid each, should be inoculated with varying quantities of blood—at least one of the flasks containing the blood in high dilution. The most stringent care in the withdrawal and replacement of the cotton stoppers should be exercised. Hiss and Zinsser use, in place of one of these flasks, one containing, in addition to the glucose, 1 gram of powdered calcium carbonate. This ensures neutrality, permitting streptococci, sensitive to acid, to develop and retain their vitality."—(Hiss and Zinsser's *Bacteriology*.)

Streptococcus infection of the peritoneum.—"Microscopically the endothelium of the peritoneum, especially of the omentum, early shows proliferative changes; the cells enlarge; their nuclei become swollen and divide by direct and then by indirect nuclear division. The cells thus produced ("macrophages" of Metchnikoff) thus produced vary in size, but some are indistinguishable from lymphocytes. The surface of the endothelial cells is covered by a layer of fibrin containing leucocytes, and there is small round-cell infiltration of the subendothelial tissues. Coarsely granular eosinophilic cells constitute a considerable proportion of the immense number of leucocytes attracted to the blood vessels of the part; this local accumulation is correlated with the diminution of eosinophilic cells in the peripheral circulation. At a later stage the cell infiltration of the underlying structures becomes more intensive and extensive, and the peritoneal endothelium is destroyed. If the inflammatory process be short-lived the endothelium survives and the fibrin is eventually absorbed, so that the formation of adhesions is prevented. If the inflammatory process is continued the endothelial cells are destroyed and adhesions form."—(Osier and McCrae's *Modern Medicine*.)

(To be continued)

Museum of Foreign Bodies from the Air Passages.—According to Leegaarde, who is touring the United States, Chevalier Jackson has a private collection of between 800 and 900 foreign bodies which he has removed from the bronchi.—*Norsk Magazin for Laegevidenskaben*.

Miscellany.

Pasteur Institutes of the World.—This list compiled from *La Presse Médicale* for November 17, 1920, xxviii, 84, comprises only the branches of the parent Institute in Paris. None of the independent institutions modelled upon it are included. The offshoots are enumerated in the order of their foundation. The Saigon branch founded by Calmette in 1890, the present director being Yersin. The Nha-Trang branch at Hue in Anam, also under the direction of Yersin and making a specialty of the bovine plague. The Lille Institute dates from 1894 and was established by Calmette. Ten years later the branch at Brazzaville was opened in the Congo for the study of sleeping sickness. The branch at Algiers dates from 1910 and was first under the charge of Calmette. He was succeeded by the brothers Sergeant and special research was made into malaria. The directors later had charge of the antipaludic campaign on the Eastern Front during the war. Since 1910 the following branches have been established in Africa: Tangiers, Casablanca, Bamakou, Dakar, Tananariva, Reunion Island, and Tunis, the latter under charge of Nicolle. One has also been started in Hanau, China, and the latest to be established is at Athens. The total, including the parent institution, equals fifteen. These are all full fledged bacteriological and pathological institutions for the combating of contagious diseases and have no connection with the so called Pasteur antirabic institutes for combating rabies alone. The so called "Pasteur" institutes in many large centers of population for the latter intent—that at Constantinople, for example—are such by courtesy only. This distinction is probably not understood by the majority of medical men.

Inhibitory Action of Sodium Cinnamate in Tuberculosis.—Corper, Gauss, and Gekler, in the Research Department, National Jewish Hospital, Denver, Colo., conducted studies on the inhibitory action of sodium cinnamate in tuberculosis, from which it was found that repurified sodium cinnamate, in concentrations up to 2 per cent., has no tuberculocidal action within three days, but is distinctly inhibitory to human tubercle bacilli in 5 per cent. glycerine agar in a concentration of 0.05 per cent., while in rabbit blood medium, both fresh and inspissated, it is inhibitory only in a concentration of about 0.2 per cent. Pure sodium cinnamate does not persist in the blood of rabbits after a single intravenous injection (1.0 to 1.25 grams per kilo) for more than one day, being present in a concentration of from 0.6 to 0.8 per cent. after one-half hour, from 0.1 to 0.2 per cent. after three hours, from 0.06 to 0.08 per cent. after six hours, and from 0.01 to 0.02 per cent. after twenty-two hours. By continuous intravenous injection of a 2.5 per cent. solution of pure sodium cinnamate a concentration of 0.08 to 0.16 per cent. of the blood can be maintained for a period of eighty-three hours in the rabbit. On account of its hemolytic action when administered over a prolonged period of time (exceeding three days) sodium cinnamate cannot be used as an inhibitory agent in tuberculosis. In vitro sodium cinnamate has both a hemolyzing and gelling action upon the whole citrated bloods of rabbits, dogs, and man.

TYPHUS FEVER AND QUARANTINE.

BY ALVAH H. DOTY, M.D.,

NEW YORK.

HISTORY furnishes abundant evidence that protracted wars which physically exhaust a nation are followed by devastating outbreaks of infectious diseases. The principal reasons for this are not difficult to determine—poverty, filth, and overcrowding—frequently associated with an inability on the part of the Government to enforce protective measures. These factors diminish individual resistance to all forms of disease. We would expect the outbreaks to be limited where the people were intelligent and the Government stable and capable of enforcing sanitary regulations. Conditions in France at the present time bear witness as to the truth of this deduction. Although this country was practically the seat of hostilities and the scene of most extreme desolation during the recent war, a quick recovery has taken place and we have no report of the ravages of what are known as quarantinable diseases—cholera, plague, typhus fever, and smallpox. These diseases are so widespread in the Far East, and, with the possible exception of smallpox, are so thoroughly identified with that section of the world that it is a common belief that they have their origin there. Since one or more of this group of diseases are always present in the East, it was expected that under the conditions of war, and following the war, there would be a rapid and widespread dissemination. There has been no disappointment in this direction.

Certain factors in the East contribute to the perpetuation of this group of diseases. The prevalent native religion is antagonistic to modern sanitary methods. The natives are taught not to respect them and the Government officials are afraid to enforce them. In other sections the Government has no interest in the matter and is quite in accord with the local popular opinion; indeed, modern sanitary methods are regarded as a menace to the health and happiness of the people. In other countries in the East, the Government, although well meaning so far as enforcement of health protective measures are concerned, is unable to make any progress in this direction, chiefly for want of money and cooperation.

Topography or climatic conditions cannot be held largely responsible for the continued presence of these diseases in the East, for we have indisputable evidence that during the middle ages they spread to western Europe and caused an enormous mortality for a number of years, because the con-

ditions now present in the East then existed in western Europe.

We may very properly believe it to be true that the spread of quarantinable diseases depends chiefly upon an unhealthy and insanitary condition of the people, associated with but little or no enforcement of modern protective measures, and that they may be surely held in check if proper means are employed. Among intelligent people and under modern sanitary regulations there is no reason to fear that an outbreak of these diseases may not soon be controlled and eliminated. Experience with modern protective methods fully justifies this assertion.

Unfortunately, the public tends to believe that since typhus fever, plague, and cholera are not controlled in the East, their appearance in the United States is apt to be followed by the same serious consequences that occur in the alleged home of these diseases. Unfortunately this erroneous belief is encouraged by some public health officials who have not had long practical experience with these conditions. Those who have dealt with quarantinable diseases only in Eastern countries, where the conditions for their dissemination are most favorable and uncontrolled are apt to be pessimistic, believing that like results may follow an outbreak in the United States. This reasoning is absurd and quite inconsistent with the facts.

Outbreaks of typhus fever have occurred at various times in New York City and have been successfully handled with no alarm on the part of the public—for instance, an outbreak occurred in the eighties and one in 1893. The latter outbreak, as it was well known at the time, was traced to some newly landed immigrants in New York who soon afterwards developed the disease and transmitted it to many others in a crowded tenement house district in the lower part of the city some days before the Department of Health became aware of its presence. General sanitary measures were promptly carried out and an exhaustive investigation was made to detect the presence of not only typical, but mild, ambulant and irregular cases—it may be said in passing that this careful investigation is the secret of success in dealing with outbreaks of any infectious disease. The cases found were removed to the hospital and their clothing disinfected and suspects were kept under careful observation with the result that the outbreak was soon brought under control and the disease disappeared.

At the time of the outbreak of typhus fever, which occurred in the eighties, the Department of Health was unable to provide proper hospital care for the cases of typhus fever discovered about the city—almost entirely in the tenement house sec-

tions—and it was necessary to keep many of them under observation in their own apartments. As far as possible the sick were isolated and cleanliness insisted upon. There was but little disinfection, for the Department of Health had very limited equipment for this purpose, yet with these simple protective measures, the outbreak was successfully dealt with.

These results illustrate what the usual sanitary measures can accomplish in the presence of an outbreak of typhus fever. If successful results were obtained with the limited facilities to which I have referred, we may be assured that with the hospital service and the complete equipment now at the command of the Department of Health of New York and other cities, there is no reason to believe that the outbreak of any of the quarantinable diseases cannot be promptly and successfully dealt with. It may be of interest to note that of the large number of cases found during the outbreak of 1893 in New York, only four of them occurred outside of the tenement and lodging house districts of the city. By far the greater number of cases were found in lodging houses, which at the time were very primitive and in a most insanitary condition. In many instances the inmates were huddled together about the floor like sardines in a box, or their hammocks were swung very close together. Under these conditions every factor was present to cause a rapid dissemination of the disease. In sections of the city where people lived under healthful surroundings, the disease did not even appear, much less spread as it did in poorer sections of the city. This also teaches us a way of successfully combating the disease.

Every necessary and reasonable means must be taken to prevent the importation of communicable diseases, for they are not pleasant visitors and they carry with them a heavy mortality. There is no justification, however, for the enforcement of ridiculous and drastic regulations which are usually associated with more or less hysteria. In the end these are sure to do more harm than good and ultimately defeat their purpose, besides they go far to impair the commercial activities of the country cause fear and discontent among the people and fail to secure the cooperation of the public which is so very essential to successful results. I have too much faith in modern sanitary science to believe that reasonable protective measures are not equal to any emergency. In the presence of an outbreak of infectious diseases, the public should not be alarmed but should be encouraged and made to believe that the emergency will be successfully dealt with, which is true.

We rely for protection against imported infectious disease chiefly upon maritime quarantine—we rely too much upon it, and not enough upon local departments of health, who should be prepared to assume their part of the responsibility if emergencies occur. An attempt to secure 100 per cent. of safety in dealing with outbreaks of infectious disease always fails. This means the enforcement of regulations which are impractical, drastic and even brutal. They cause unnecessary inconvenience and hardship for those who travel by sea and seriously injure the business of the country. Such measures have gained for maritime quaran-

tine an unenviable reputation since its establishment in Venice during the fourteenth century. In the early history of quarantine, vessels arriving from foreign ports were required to place their cargoes on deck for a number of weeks for so-called purification, however, the actual media of infection—the passengers and crews—were allowed to go ashore whenever they pleased. Vessels and their cargoes were sometimes sunk or burned to prevent the transmission of infectious agents. Such methods were in force as late as the eighteenth century, and I am sorry to say it must be recorded that unreasonable measures, although to a less degree, are still in force and may be recognized at the quarantine stations throughout the world.

When maritime quarantine was first organized the "fomites" theory which holds that any exposed article is able to transmit infectious agents, was supreme—although this is a fallacious belief, it unfortunately still exists to a certain extent. It is only within the past twenty-five or thirty years that those who have given careful practical investigation to the subject have been convinced that the incitants of infection are commonly transmitted by persons and not by things. This knowledge is of great value to those who are responsible for the public health for it simplifies their work and allows them to give close attention to the examination and observation of persons brought under their jurisdiction, who, when infectious diseases occur, constitute the important medium of infection and not vessels, cargoes, baggage and the like.

The function and need of maritime quarantine would be greatly diminished if each section of the world enforced proper sanitary regulations within its boundaries and was mindful of the health and comfort of others and careful to note and publish the presence of outbreaks of infectious diseases among its people, in order that the various countries may better protect themselves—however, this condition is not to be expected, at least for a long time, therefore, for the present we cannot dispense with quarantine, however the danger of imported diseases and their sequelæ, both in transit and at the port of destination, which involves loss of life, great expense and injury to commerce, and the detention and annoyance of those who travel by sea would be reduced to the minimum if persons from infected districts abroad, upon arriving at the ports of departure, were promptly and properly dealt with and kept under daily observation and inspection, sufficiently long to insure reasonable evidence that they were not a menace to health. This would constitute the first and most valuable line of defense against imported infectious diseases. Aside from the greater protection of life and health it would be of financial gain to all involved. It is within the power of the Federal Government to enforce this important method of protection.

It has been proposed that the Federal Government, in dealing with the present outbreak of typhus fever, require the detention at quarantine for a number of days of vessels arriving from foreign ports. These vessels include some of the largest steamers which ply between New York and Europe. It is also proposed to include the detention of first-class passengers as well as the second cabin and steerage passengers.

During my quarantine service which covered a period of fifteen years, I never found a case of typhus fever, plague, or cholera among the first class passengers on vessels arriving from foreign ports, and rarely a case of any form of infectious diseases, although cases of quarantinable disease were frequently detected among the steerage passengers of these vessels who had come from infected centres, principally in the East.

First-class passengers live and travel under healthful environments, they rarely visit infected centres; if so, they protect themselves while there; furthermore, they have nothing to do with steerage passengers while on shipboard. Therefore, it is manifestly improper and unreasonable that they should be held at quarantine except so far as it is necessary to ascertain their physical condition, where they have been for an indicated period prior to their embarkation, and to obtain their home address. After this information was obtained and they were found free from infectious diseases, they were allowed to proceed to the city. Although the result of this plan was kept under careful observation during my term of service as Health Officer of the Port, there was no evidence presented that any unpleasant occurrences followed.

Among second cabin passengers there may occasionally be found one or more of the type of steerage passengers and these may have previously affiliated with them in transit from the interior, but having sufficient funds conclude to travel second class. This must be borne in mind in dealing with this grade of passengers. Steerage passengers, particularly those arriving from the East, are commonly ignorant, unclean in their habits and usually come from centres where filth and poverty, and overcrowding exists, and where some form of quarantinable disease is present, therefore, they constitute a distinct menace to the public health and should be subjected to a most careful examination at both the port of departure as well as the port of destination. The examination should be made not only to detect well marked cases of diseases, but more important still, the *mild ambulant or irregular ones which constitute the most dangerous medium of infection*, for they are quite apt to pass unrecognized and transmit infectious agents to others.

In dealing with suspected groups, either among the passengers or crews, no examination is complete without the use of the clinical thermometer, yet the great value of this instrument depends wholly upon the extreme care with which it is used. It must be of the best make, carefully tested and there should be a sufficient number on hand to prevent unnecessary delay of the vessel. The register should always be examined immediately before placing it in the mouth of the person under observation. The details of the examination should be under the personal observation of a dependable officer in order that nothing may occur to render the examination worthless. In many instances, particularly during the yellow fever period, persons under observation at the New York quarantine were found to have drunk ice water or placed pieces of ice in their mouth just before their temperatures were taken. Special means were necessary to prevent this. The thermometer when properly used is

particularly valuable in the detection of mild or ambulant cases and during the stage of invasion.

Delousing as a preventive measure in dealing with typhus fever is receiving at the present time very extended consideration. All newly discovered sources of danger, so far as the transmission of disease is concerned, are quite apt to be promptly accepted without reservation. For instance, when the germ origin of disease was announced it was believed that danger existed everywhere—in food, drink and almost every article with which we come in contact, and some time elapsed before it was understood that only certain organisms are dangerous, and that we might safely eat and drink and enjoy life without fearing disaster from this source. A similar condition prevailed when it was learned that the variety of the mosquito known as the "Stegomyia" was the medium of infection in yellow fever. Immediately this insect, which is a common one, was looked upon as a constant source of danger, which is untrue, for it is only a menace after it has bitten a person having this disease—at other times it is as harmless as any other variety of the mosquito.

So far as I am aware no one doubts that the body louse is a medium of infection in typhus fever and it has already been proclaimed as a most dangerous parasite, notwithstanding the fact that it is commonly found in almost every country in the world and generally regarded as harmless. The fact is, that it becomes a dangerous factor only after it has been attached to the body of a person having typhus fever. At other times it is not to be feared, although quite uncomfortable to its host.

Without discussing other possible means of infection in typhus fever, or the extent to which delousing should be performed, I will cite the quarantine experience of fifteen years regarding the treatment of passengers arriving from typhus fever infected districts. During this time foreign vessels were constantly arriving at this port bringing immigrants who had recently left sections of the East where typhus fever was present—there was plenty of evidence that a large per cent. of them had body lice. Within the period to which I refer, a very extended outbreak of typhus fever occurred in Russia and I visited that country with the view of becoming familiar with the environments and surroundings of those who were arriving here from the infected districts. I found that they came from sections of the country where the most insanitary conditions existed and that poverty, filth and overcrowding was in evidence everywhere, and with but little or no Government supervision; furthermore, these people who came under my observation were practically escaping from Russia, for they had been denied permission to depart and were subject to severe punishment for doing so, therefore it could not be expected that they would give any attention to methods of protection against disease. Upon reaching New York they were subjected to careful examination and if found to be well, and there were no suspicious cases under observation, they were released without delousing or the disinfection of their clothing. If typhus fever or other quarantinable diseases was found on board, the clothing of the sick was disinfected and the remainder of the steerage passengers held

for observation; however, no general disinfection was performed. During this period, although these people went to every part of the United States, I know of no instance where an outbreak of typhus fever followed.

I have no desire to belittle the danger of the louse as a medium of infection in typhus fever; however, I believe the importance of absolute delousing is overemphasized. As a result of experience, I do not believe it is necessary to carry out this process except in dealing with cases of typhus fever or cases suspicious of this disease. Unless some line of demarcation is decided upon, this matter will be dealt with from a theoretical and hysterical standpoint and not in a uniform manner which is so essential to success. The louse is an objectionable parasite and delousing may well be insisted upon as one of the desirable measures of personal cleanliness, but not as an indispensable and vital safeguard against pestilence—furthermore, this renovating process should be carried out at ports of departure and not at United States ports. The fact is that the most valuable and successful means of preventing an outbreak of typhus fever is an extended and exhaustive examination to detect not only well marked cases, but the mild or unrecognized ones which are chiefly responsible for the dissemination of infectious diseases throughout the country.

I may say in conclusion that every city and town throughout the United States should be under the observation of an efficient health officer who is capable of dealing promptly with outbreaks of infectious diseases or suspects which may appear in their locality, possibly due to some infected person who has passed quarantine unrecognized. These officers should be instructed as to the importance of a thorough and extended investigation whenever a case of infectious disease has been discovered or when suspicious cases are under observation and that they should know the danger of mild or unrecognized cases as media of infection. Unfortunately many of the small towns throughout the country have no health officers—frequently the health officer is a layman, entirely incompetent to deal with emergencies, and it is largely for these reasons that extended outbreaks frequently occur throughout the United States.

147 WEST FIFTY-FIFTH STREET.

A DISCUSSION OF SOME DETERMINANTS OF MORBID EMOTIONALISM.*

BY TOM WILLIAMS, M.B., C.M.,

WASHINGTON, D. C.

THE subject I have to speak upon is, "Some Determinants of Morbid Emotionalism," or rather "Emotivity." I should first say what is meant by "emotivity." Emotivity is a state which hitherto, until this present century, was dealt with in a purely introspective and observational manner. Indeed, it was rather neglected by the more modern psychologists. Without psychologizing about emotion and emotivity we must understand that there can be reaction or reactivity without a state of feeling, which

is emotivity, even in the case of the unicellular organisms, which have no differentiated nervous systems. We cannot conceive that an ameba, for instance, which is repelled by a particular stimulus, does not have, at that moment, a state of feeling. And as we pass up the animal scale we are able to observe the difference between the manifestation of what we call a state of feeling or emotion, and the more purely purposive manifestations which we associate with the cerebrospinal nervous system. So that we must remember that an emotion is not merely a function of higher psychic perception, or a critical process; it is a function of the whole organism, and in it the whole organism participates.

What shall we regard as morbid in emotivity? We are all subject to emotivity, indeed the individual who is not emotive is not normal, he is morbid. For instance, in regard to a speaker—and I am now going to have recourse to the much-derided process of the ultrapsychologists, namely, introspection—I propose to introspect my own feeling in appearing before this highly distinguished audience. Instead of having the feeling of deep emotion, which I should have perhaps, I find myself in a state, at this moment, of comparative indifference. I think that is probably a morbid phenomenon, because one should face an audience in a state of high emotivity. That is, perhaps, due to a long process of attrition, of wearing down, which I have undergone, so that I am sorry I cannot reach the state of necessary emotionalism which our colleague Crile called the "kinetic drive." Prof. Robertson last night exhausted my "kinetic drive," at least, what of it remained after listening to the address of the president yesterday; for he aroused in me not only emotions of appreciation for the exceedingly erudite inductions he performed, but also one or two of the combative or antagonistic reactions of Crile. These, not having resolved, remain, according to some colleagues whose doctrines I do not share, in a state of conflict in what they call the unconscious, and this should to them account for my comparative indifference in the present situation. The real explanation is in habituation plus a certain fatigue.

Having disposed, then, of the lack of emotion, let us try to find out what kind we ought to consider morbid. We should not consider as morbid an individual who has been suddenly bereaved of some one he loves very dearly and falls into a state of depression. But we should call it morbid if that state were to continue for a period which we consider unduly long. But I cannot see that we are able to draw a hard and fast line to determine when an extraordinary state is one of morbidity and when it is not, whether it be six months, or twelve months, or eighteen months, or for life. Who shall say when a widow should doff her weeds? I speak only in a symbolical sense, taking the widow's weeds as denoting a state of highly disturbed emotivity. Shall we call it morbid when an individual faced by imminent danger which he does not know how to avoid falls into a state of terror? We do not do so. Why, then, do we say of certain individuals who do fall into these states that they should be regarded as morbid, while of others we say they should not? Is it not a matter of convenience of description and teleological judgment on our part? In the early days of the war—at least in America—

*An address delivered by invitation before the Medical-psychological Association of Great Britain and Ireland, July, 1920.

it was the fashion to exalt the horrors of the battlefield and to say that no human being could face the awfulness of the emotions aroused thereby—that is, that the emotions could not be dominated by the will or by reflection or by discipline. That was found, before very long, not to be the case. It was found that even the most terrifying situations, which were at first viewed with such alarm as not being tolerable, were conquered by the education of the men in the feeling that such situations ought to be faced. And when that is the case, the average individual could face the situation, no matter how terrible.

That leads me to speak of one of the factors in the determination of the emotivity we consider morbid. If that individual soldier—and it is as true of situations in civil life—can learn to face such situations, and with impunity, or with equanimity, why is it that other individuals do not face the situations with similar equanimity?

There are three kinds of reason perhaps, and I propose to say only a few words upon two, devoting the rest of my time to the third.

The first type is that described in the president's address of yesterday—the state of inadequacy of neural reactivity, whether that is due to an active toxic influence preventing due elaboration of the processes of which we shall speak later, or whether it is due to actual physical deficiency of the neurons induced by what we call organic disease.

We all know of the unreasonable irascibility, the euphoria, and the depression at different times of the general paralytic, whose cortex is in a process of disintegration. We know of the unreasonable terror and the unreasonable responsiveness to mild stimuli of the patient intoxicated by such a poison as that of the Eberth bacillus in the course of typhoid fever. We know the same kind of patient who is alcoholic.

These pathogens we know, but while we know of the unreasonable depression of mind and spirits of the individual we call melancholic its pathogen escapes us. But while it is premature to attempt to say that such conditions are due to any kind of physical deficiency, or to any kind of physical presence which we do not know, as the president endeavored to show us yesterday—and I may say I fully agree with his train of reasoning and with his conclusion—yet I think we can find a type in the normal individual who has for example, "the blues" which has been induced by a nocturnal debauch, the blues of "the morning after," which we cannot fail to recognize as a physical state of a toxic nature. Many such persons cannot form true judgments, and hence the whole world seems blue; they are in a state of morbid disturbance, and their affectivity is in a painful state on account of their general intoxication, not necessarily impinging upon cerebral elements, but perhaps impinging upon end-organs in the viscera (cenesthesia), and producing a painful state, which we do not call pain, but which we designate distress. This is a state which, not only directly but perhaps through the peripheral nerves, affects the central nervous apparatus, so that the feeling provoked is one of distress, painfulness, and morbid affectivity. And we know how rapidly that state disappears in the course of nature, or by the intervention of the

calomel-giving doctor. These then are emotional perturbations of chemical genesis.

The *second type* of morbid emotivity which I shall speak of is that which seems to be inherent in certain individuals, that is to say, constitutional emotivity (Dupré). I question whether many of these are not really in the third category of which we shall speak, the hereditary element in them being not so important as so many of us are apt to suppose. (See my study on the Genesis of Phobias in International Clinics, iv, 1919.)

The *third type* is what I like to call the emotivity which is induced—that which is bred by induction. It is by far the commonest, in my own mind and experience; but it is perhaps the least common in the experience of most of my audience, who perhaps deal with individuals of the first class. The patient who is brought to me because of emotivity, because of what he calls "nervousness," can often be found to have fallen into this emotional state because of some stimulus, not of a chemical, but of a physical or dynamic character, of the physiological kind we call psychogenetic. That is to say, he has met with a circumstance, or a series of circumstances, which have aroused in him an emotion which he is unable to transcend. The person has previously been normal; often he is in other respects normal except in reference to this particular kind of incident which aroused the emotion. Such patients as we call "phobiacs" are the prototype of that situation. Perhaps I cannot do better than read the notes of one such case, and perhaps allude to one more, the particulars of which I have brought with me, so that we may have the basis of a discussion on the mechanism of such cases.

The first case is that of a boy, *æ*t. 8, who had developed hallucinations, which had occurred only when he was alone and whenever he was alone. The hallucinations were accompanied by a loud cry and a twisting backward of the neck and contortion of the body, so that a distinguished professor regarded him as epileptic. His father and maternal uncle were declared to have had similar attacks in childhood. The mother was over-anxious about the boy, and was "hysterical" and uneasy when he was out of sight. Examination showed no physical signs of disease of the nervous system or of any other system. In amnesia I found him to be a very sensible little fellow. My questioning soon showed that the hallucinations were not true ones, and that he never actually saw, felt, or heard what he feared. Since he clearly recognized that he had actually never seen anything to be afraid of, it was a simple task to convince him that the wild animals he feared were only imagined, that, in fact, there was nothing to fear, and that he was quite safe, even when alone. It was impressed upon him that he must learn to be a manly boy and to depend upon himself. In order that he might learn not to be so timid, firstly he was told to go out alone every day, at first half a block, then a whole block, and finally round the corner, all the time remembering the need of manly behavior. Secondly, he was told that he must go to sleep alone, so as not to be such a trouble to his parents. Thirdly, he was shown exercises to suppress the wriggling tendencies of his body. Having convinced the child of the unreasonableness of his fears, the parents, especially the mother, were dealt with rationally. It was explained to them that his trouble was a phobia against being alone—an affective state induced by the idea that something dreadful might happen to a little boy unprotected by adults—an idea induced by the foolish anxiety of his mother, of which he was very well aware, whenever he was out of her sight. His morbid reaction had become a habit, which, with practice in self-reliance as outlined, could be overcome. As a result no further attacks have occurred for ten years.

That is a very simple example of induced emotivity, brought about by nervous apprehensiveness on the part of the mother, who was alarmed whenever the boy went out of her sight; and he showed the alarm very strongly, imagining possible dangers. As he found no real dangers, he seized upon the only danger which looked like being real—that connected with farm animals, that they might jump on his back, and from the likelihood it was easy to imagine that they did so. When the thought seized him he would utter a loud cry and have a so-called automatic epileptic seizure.

The second case is more complex.

A woman of thirty-three, who, having frequent attacks of palpitation, polypnea with chilliness, moisture, and cyanosis of the extremities, rigidity and pain in the neck and back, nausea, and a sensation of great weakness and dizziness, suspected she had heart disease, of which she had a great dread. Examination showed no physical disease, the only signs present being those of hyperthyroidism. She had been an exceptionally strong girl, without worries except anxiety over the health of an invalid mother. She had always feared high places, but thought nothing of it, as the other members of her family all felt the same way. There was no fear of the dark and no social timidities other than a dislike of being conspicuous. Having an overpowering fear of losing consciousness on account of this palpitation and heavy sensation of oppression, she had for eight years been unable to remain in a church or theater or, unless accompanied, to cross a wide street.

When asked to relate the first occasion upon which she had experienced the trouble she was able to recall, after some effort, that in a small, ill-ventilated church, on a hot summer day, she had begun to feel an overwhelming sense of illness during the sermon. The compulsion to leave the church was intense, but as she sat near the front, well back in the pew, she was unwilling to create a disturbance by leaving, so forced herself to remain. This attack was followed by others, which occurred more often as time went by, although at first avoidable by sitting near the door.

The diagnosis was that the agorophobia and claustrophobia were hysterical in origin, arising from the powerful suggestion of the recollection of a particular experience, made efficacious now only by the timorous imagination of the patient. For the hypermotivity of hyperthyroidism is occasioned by numerous circumstances, whereas in her case emotion was only contingent upon very definite circumstances. Hence the hyperthyroidism was considered as secondary. Relief of the chronic emotional strain was believed sufficient to cure this.

Reeducation was forthwith begun. The patient was at first unwilling to undertake it, giving the excuse that she had never been willing to introspect, but she accepted the necessity of doing so when it was explained that a person is under an obligation to know himself and that it is futile to oppose this need. It was explained that her dread of a close or open place was due to her ignorance of the mechanism of the consequences of a wrong way of looking at things and the consequent emotions, and that only when she obtained a true insight into her own psychological machinery would she be able to control it. The power of induced ideas and the feelings produced thereby were explained to her. After a while she accepted the explanation, adding: "It must have been fear, for on the first occasion, when leaving the church, one of the maids said: 'What frightened you?'" She added that she was naturally a self-contained person and was relieved after the relating of her feelings. When asked to write an account of her view of her own psychology she did so, showing a clear grasp of the power of conceived ideas, and concluded by saying: "It is difficult for me to understand that these signs of illness are not illness at all, but are caused by an induced impression. But now with the assurance that there is absolutely nothing wrong with my physical makeup, my problem seems to be to rid my mind of the fear which has unconsciously but completely controlled by thought."

So the next step in the treatment was to demonstrate

the truth of this. I accompanied her to a large square and made her cross it alone. This feat accomplished, though under great strain, she declared that it had been performed better than at any time since the start of the trouble. Later she attended church with only momentary discomfort, when she reasoned concerning it and concluded that nothing could happen. I concluded with the final adjuration that since she realized she was well, all then depended upon herself. She remains well a year later.

Thus, violent, persistent, long continued agoraphobia and claustrophobia were traced to a single incident upon which they were dependent. They were removed in less than a week by efforts directed toward giving the patient an understanding of their mechanism, indeed, compelling her to grasp it and then compelling her to take an exercise which afforded a practical demonstration.

The following is another case showing the real determinant of morbid emotivity. It is one of long standing fear of death which was removed in a week. The rapidity with which the genesis was discovered in this case is not singular, in fact, I have found it the rule.

Last spring a man, aged 30, was referred to me by Dr. Sterling Ruffin because of a nervous breakdown. Superficially and in his own estimation he appeared to be simply agitated, terrorized, and quite incapable of conducting the business which had brought him to Washington. His face was congested, his eyes were bloodshot, and he trembled violently. Indeed, the friend whom I first saw doubted his willingness to see me. In spite of this, a single interview sufficed to discover that this abject picture was not caused by physical disease, but was the result of phobias. The origin of these was ascertained in part at the same interview, and during the following few days the genesis was penetrated adequately to permit the man to return to his Western home, no longer incommoded by the morbid fears which had incapacitated him.

This man's fear had originated during the excitement and horror caused by the bursting of a large dam in the city where he lived. His efforts to reach his home and rescue his mother were impeded by the crowd, whereby an anxious terror was induced. This persisted as a fear of water and of storms. Eventually the wind became the most conspicuous feature which aroused fear. Fire would also do this. Recently the phobia was becoming associated with circumstances more and more numerous and he had become less and less fit for his business, which was of an exacting nature. He had been sent to Florida for a change, and while there got better. He quickly relapsed, however, upon returning to work. The real meaning of these phobias was fear of death—and it was this that had to be dealt with before his peace of mind could be restored.

It was very necessary in this case that each step he took should be expressed by him in writing before my review. It was in one of these exercises that he made the significant declaration: "Perhaps I don't amount to much anyway." He made the further statement: "I have concluded I will be just what I make myself."

This patient was the antithesis of some of those we often see in that so far from having a sense of inferiority he felt himself to be a highly superior individual. He was an only child, spoiled, and things had always gone well with him, even in business, where he was protected and almost petted by the heads of the firm. It was not until the sense of humility was aroused that he was able to deal with the groundwork of his fears.

What is the lesson of that second case for this study? Is it not that here is a case of a state of chronic emotivity (which was pervading more and more the patient's whole personality, so that it was becoming difficult even to go out of the house at all, so that she would not go out alone), being *entirely*

due to a particular stimulus which aroused an emotion only in a particular situation? We were here in the process of development of what has been called pantophobia*—a fear of everything, which this patient would eventually have developed, which is often declared to be a constitutional emotivity and therefore inaccessible to therapeutics. In reality, this pantophobia, when properly penetrated into, was a particular individual phobia in a definite situation, the clarification of which enabled the patient to understand the psychological processes which had eventuated in the emotivity whereby, by a considerable effort of the will which enabled her to grasp the new concepts, she was caused to get rid of the consequent emotivity entirely.

Therefore in such cases—and they are the vast majority—the emotive state is purely induced. It depends primarily upon perceptual elements; the patient has perceived the situation, just as the ameba perceived a situation, a stimulus from which it recoils, because it creates in it a state of unpleasant feeling. The individual perceives a stimulus which creates a state of unpleasant feeling—an impression which she seeks to avoid. There is a teleological reaction which she does not know how to avoid, because she does not know the nature of the stimulus. Why? Because she is not possessed of adequate knowledge to envisage that stimulus correctly in its true relation to herself and to others. In other words, it is a fault of commission, psychologic induction of cognition which permits of the development of the kind of emotivity which we describe as morbid.

Therefore the emotivity must be attacked, not directly by the soothing process of substituting another emotion for it, because that does not destroy it, it only covers it over temporarily. It must be done by attacking its primitive cause, which is cognitive. Because of that the patient fails to appreciate the true situation with which she is faced, and breeds from that false view an emotion which, under the circumstances within her knowledge, is perfectly legitimate and proper. We are, therefore, dealing fundamentally with a false belief, a pathogen not primitive emotion at all. We have the best prototype in the conditioned reactions of the dogs of Pavloff's experiments, of which, of course, we all know.

It has been said that the emotion should cease as soon as its determinant has ceased. That is true, and in most cases that is what happens. The psychological stimulus from without, which creates the emotion, disappears, and the patient is then no longer in a state of emotivity. Why in some cases does it not disappear? It is simply a matter of failure of resolution of the problem by the patient. The patient who has lost a dear one is gradually able to become reconciled to it, and to say, "Yes, we have lost this dear friend, but our life had to be lived, and there are others alive who need us, and so we should not always continue to mourn," and so on. And the other factor, so-called time, which means the gradual onset of comparative indifference because of other interests, comes to the rescue also.

In the other case the stimulus does not actually

*A contrast in psychoanalysis where a case of pantophobia was successfully dealt with by methods not those of Freud (J. Abnorm. Psychol., 1911).

cease; it only appears to do so. As a fact, kept to the fore by memory, the stimulus becomes more and more strong, and the stimulus is followed by the patient's reproduction of the emotions appropriate to stimulus, although not to the apparent situation. I will read to you a letter I had just before leaving, which very well shows that:

Whenever I read anything that seems to corroborate my fear I cannot wait for some one to help me to forget it. The trouble is that there are certain things that I have heard and read appropos of the same idea (that of fear) that have been lingering in my mind for years to terrify me. I should have talked to you long enough when you were here to allow these things to rise to the surface. I left the meeting that night partly because, when I found you speaking about phobia, I was afraid you might tell or delineate too clearly the effects of fear. Whenever I write or speak of it I want to hurry past it. I had to force myself to write out in that summary the exact words, lest thinking of it might make it worse. After the psychoanalysis* was such a failure my will-power seemed to become more and more flabby.

Then the war made it evident that the worst could happen; so it is difficult for me to get adjusted right away to the thought of even trying again to get better. However, under the stimulus of your visit, I find some things much easier.

Although I cannot voluntarily yet put myself in a really difficult position, anyhow I am this much better that I find myself considering such undertakings as a trip to a summer resort, which was heretofore fraught with too many dangers to be at all attractive, and I seem to be willing to enlarge my sphere in a way I did not consider at all some weeks ago.

You see that there the patient realizes very well how stimuli might mount to sensitized receptor situations, and hence has too much fear of their import. And she knows that when she comes into contact with any matter which will touch those receptors she will pass into this panic. This patient, whom I saw for two days only, had had these fancies since sixteen years of age.

Another person who had pantophobia (see "Prevention of Suicide" *Am. Journal of Insanity*, 1915), was a man, æt. 27 or 28, who feared everything and was in a state of complete inadaptability on account of this intense emotivity. He had a strong belief that his condition was hereditary, because on both his father's and his mother's side the heredity was extremely bad: there were asylum cases, all were neurotic, one brother died of epilepsy, and the other was a tramp—left his home young for the purpose of being a tramp. Yet in ten days that patient was restored to efficiency because it was discovered that the source of his fear though not a single incident, yet was a series of incidents induced by a very unwise relative who, having the bringing-up of the boys, believed that fear was a necessity for good discipline, and that only by fear could they be well trained. He therefore carried out stern measures and deliberately induced fear in the boys. This persisted in this man until he was 28 years of age and unknown to him in regard to its mechanism. This man has since faced difficulties in securing position in his profession, that of attorney in a large Western city. He has married, has two children and since the treatment has never had a relapse. That, therefore, is a very important case

*Alluding to a period of four months of treatment by a psychoanalyst without benefit. He had persisted in searching for a repression, of which there was no evidence, to account for symptoms of which the mechanism was clear enough.

from the point of view of differentiating between the condition which we label "hereditary," and that which can be induced and reconditioned.

Our psychotherapeutic measures then are those which are adapted to the reconditioning of patients who are in a state of emotionality which we regard as morbid.

1716 K STREET, N.W.

ACUTE PURULENT OTITIS MEDIA IN CHILDREN.

BEING A DISCUSSION OF THE ETIOLOGY, BACTERIOLOGY, DIAGNOSIS, COURSE AND PROGNOSIS, PROPHYLAXIS AND TREATMENT OF ACUTE PURULENT OTITIS MEDIA IN CHILDREN, WITH A PLEA FOR MORE CAREFUL INSPECTION OF EARS, AND MORE PERSISTENT TREATMENT OF INFECTED ONES.

By JAMES G. CALLISON, M.D.

NEW YORK.

THE preservation of the special senses, especially those of seeing and hearing, is secondary in importance only to the saving of the life of the individual. Infections of the eye, easily seen and often alarming, both to the physician and to the parents, usually receive the attention their importance warrants. Infections of the ear, often insidious in onset and free from systemic manifestations, frequently fail to receive the consideration their seriousness deserves. This is amply borne out by the large numbers of adults encountered who are deaf or nearly so as a result of ear infections dating from childhood. It is only at a later stage of life, when the impaired hearing is an economic or social handicap and the damage to hearing is irretrievable, that a persistent effort is made to cure the discharge. In frequency of occurrence, acute purulent otitis media forms the third great group of children's ailments. Involvement of the respiratory tract—colds, acute adenoiditis and pharyngitis, bronchitis, and pneumonias—form the first group; intestinal upsets the second group, and ear infections the third group. As all the acute infectious diseases of children, together with the ordinary colds, list acute purulent otitis media as complications, it is most essential that each physician who is called upon to treat these little patients should be able to diagnose the condition and intelligently direct its treatment. It is the aim and object of this paper to contribute something to this end.

Etiology.—Acute purulent otitis media in children is practically always secondary to a nasopharyngitis. I say "practically" out of deference to members of the profession who claim that sometimes there is another method of infection. A very large majority of the children that suffer from running ears are also sufferers from adenoids, and are temporarily or permanently mouth breathers. The extension from the pharynx to the middle ear occurs in two ways. In the ordinary "colds" of children the adenoids are swollen and interfere with breathing and drainage from the epipharyngeal space. As the child lies on its back the secretions from the nose collect in the epipharynx and are added to the secretions of the pharynx itself. In the act of swallowing, coughing, or gagging, there is a violent

contraction of the pharyngeal constrictors, together with the palatoglossus, palatopharyngeus and levator palati muscles, causing a reduction in size of the epipharyngeal or postnasal space and the opening of the eustachian tubes. By this means contaminated secretions are forced from the epipharynx into the middle ear. This infectious material initiates an inflammatory process, and as this is established in the middle ear the mucous membrane becomes swollen and congested, and the otitic end of the eustachian tube is occluded, resulting in a closed abscess cavity.

In other instances of inflammation of the mucous membrane of the nose and throat the infection is severe from the start, and there is a rapid spread of the inflammatory process by lateral extension along the pharyngeal and nasal mucous membrane to neighboring structures. In this process of lateral extension the eustachian tubes participate and the infection is thus carried into the middle ear. These are the cases, of course, that give the more violent, fulminant symptoms. And they are also, in my opinion, the cases that respond more rapidly to treatment, in that they are recognized and receive treatment at an earlier stage. From this class, also, are the cases that go on to rapid mastoid infection, in spite of the most careful treatment.

In such systemic infections as typhoid fever and lobar pneumonia, proved to be primary bacteremias, there may be a true hemogenic implantation of the infecting organisms. This may be true also of infections of unknown nature, such as influenza. However, such a method of initiating an acute purulent otitis media is not proved. In scarlet fever and measles, infections of undetermined nature, the path of extension to the middle ear is not known. The otitis media may be due to the specific organism, whatever that may prove to be, responsible for the condition. As a streptococcal pharyngitis is a prominent symptom of both of these conditions, however, I am of the opinion that the ear infection is of a streptococcal nature, and that the involvement is by direct extension.

Bacteriology.—The bacteriology of acute purulent otitis media in its early stages, investigated by cultural methods, should prove an interesting field of investigation for the department of bacteriology of some of the ear, nose, and throat hospitals. As usually returned, the report on smears from acute ears is that of a mixed infection, which is undoubtedly correct. These cases are all infected from the throat, and the bacterial flora of that region is always varied. The pathogenic organism predominating in the tonsils and adenoids seems to be the *Streptococcus hemolyticus*, and this organism predominates in ear cultures at the later date when cultures are called for. Next in importance to the otologist is the *Streptococcus capsulatus*, or the *Pneumococcus capsulatus*, No. 4, as it has come to be called from its agglutination reaction. This organism is responsible for the severe, destructive, insidious mastoid infections so much dreaded by the otologist. These are more common in adults than in children. Of less importance are the *Streptococcus viridans* and the pneumococcus infections, while staphylococcal infections are only of secondary importance. There is a great variety of bacteria,

non-pathogenic, carried up from the epipharynx with the infectious material, but these undergo rapid bacteriolysis and phagocytosis and disappear, bearing no causal relationship to the ear infection.

Diagnosis.—There is but one method of detecting all cases of acute purulent otitis media in babies and small children in the early stages—that is, a direct inspection of the tympanic membrane. In no other way can the changes in the contour and color of the drum and auditory canal be appraised at their true value. With the number and perfection of the pocket battery otoscopes now on the market, there is no excuse for inability on the part of any physician who is called upon to see children to make such an inspection. As has been said in regard to another instrument allied to another specialty, it might be a good plan to tie the otoscope to the stethoscope. The importance of this aural inspection in the examination of children comes next after the abdominal inspection, and is of much more importance than the examination of the chest. The reason for making this hard-and-fast statement is that the otological condition is amenable to treatment, while the response of chest conditions to the administration of drugs is at least questionable. Aside from the redness and bulging of the drum membrane in acute purulent middle ear infections, there may be no other symptom. There may or may not be pain in the infected ear, and the symptom of the localization of pain in children is easily overlooked or misinterpreted. In addition to the pain in the middle ear, there may sometimes be a slight pain in the tragus on pressure. Likewise, there may also be pain over the mastoid, especially at the tip, in the early stages of the infection. Fever may or may not be present as an accompaniment of acute ear infections. If fever is already present, as it usually is prior to the purulent invasion, its significance in a child in the midst of or recovering from a cold, measles, scarlet fever, or other acute infection, is difficult of interpretation. It must be remembered also that simple pharyngitis in children may give a temperature of 102° or 103° with no other involvement.

In some cases these children look septic to a degree difficult to explain in the absence of a careful ear examination, but this is not a constant symptom. In some rare cases, where the eustachian tube remains open, pus may be present in the middle ear without bulging of the drum membrane. Such cases present extreme difficulties of diagnosis, and sometimes leave experienced otologists in doubt as to the actual condition present. At a later stage of the infection there is a discharge from the infected ear, and the diagnosis is established. But the condition should not be allowed to progress to that extent where anyone can make the diagnosis from a dirty pillow. Of the four cardinal symptoms of acute purulent otitis media, pain, fever, discharge and bulging of the drum membrane, only the last is constantly present and unmistakable in its interpretation. The extent of the change in the fundus of the canal varies from a simple "bellying" or "ballooning" of the membrana tympani to a collapse of the superior canal wall, with a pushing outward of the membrane to such an extent as to obliterate the fundus landmarks, or even to render it doubtful where fundus and canal wall join each other. But

the question is not so much one of extent of the changes in contour as it is one of whether such changes are present.

Course and Prognosis.—The course of acute purulent otitis media may take one of three general variations. These, in the order of their desirability, are as follows: First, an uncomplicated progress to a cure. Second, there may be the development of a mastoiditis, with operation and recovery. Third, and most undesirable, the ear may continue to discharge, through neglect or improper treatment, and become a case of chronic purulent otitis media, with the accompanying loss of hearing. If the disease is terminated without undue delay, and the drum membrane is returned to normal, there will be no effect on the patient's hearing, which will return to the normal for that individual, that is, to his normal of before the attack. If the process involves the mastoid bone, with destruction of its cellular structure, and a proper mastoid operation is performed, with recovery without undue prolongation of the middle ear infection, then the hearing should still be returned to the condition in which it was before the ear became involved. If the mastoid operation is incomplete, and the middle ear infection continues for an undue time after the operation, with the formation of granulations in the middle ear and attic and the ultimate existence of scar tissue after healing has occurred, then the hearing will not return to normal. If the existence of the mastoid involvement is overlooked, then the patient is liable to the complications of a neglected mastoiditis—brain abscess, meningitis, sinus thrombosis, and septicemia. A discussion of these, however, is beyond the proper limits of this paper, but more properly comes under a discussion of mastoiditis.

In those neglected or improperly treated cases of acute purulent otitis media that are allowed to become chronic the amount of useful hearing that remains to the patient is problematical, but will be slight. In addition to this loss of hearing, the patient rests under such a load of danger to his life that he is not usually accepted as a risk by life insurance companies until he has undergone a successful radical mastoid operation. Aside from this danger to life in chronic purulent otitis media, the care of such an ear is a burden to the patient, and he is, in many instances, obnoxious to those associated with him because of the disagreeable odor to the discharge from the ear.

Prophylaxis.—There is only one important item in the prophylaxis of acute purulent otitis media in children: Adenoids must be removed from all children who show any tendency to mouth breathing when asleep, and from all children subject to recurrent colds. Even in the absence of these symptoms, if a digital examination of the epipharyngeal space reveals the presence of adenoids in excessive amount, they should be removed. Mother and nurse must be repeatedly queried as to whether the child sleeps with its mouth open. Too much stress cannot be laid on this one condition. If the child's whole postnasal space is filled with adenoid tissue, or nearly filled, it will, with the slightest pharyngeal congestion, "catch a cold," and run the risk of having this cold extend to the middle ear through the eustachian tube. In the few cases in which nasal obstruction occurs in children this must be relieved,

If the child continues to have a "running nose" after a complete adenectomy in competent hands, then the question of an ethmoidal infection must be considered and, if present, must receive the proper operative treatment. Nasal sinus infection in children is rare, as all the sinuses are rudimentary in character at the ages under discussion. In addition to removing adenoids and nasal obstruction and infection when present, that series of precautions calculated to prevent children from taking colds should be instituted, if anyone knows what will accomplish that result.

Because of its importance in relation to acute purulent otitis media in children, a word here as to the technique of adenectomy may be permissible. The preferable method for the removal of adenoids is the use of the La Force box adenotome. Under general anesthesia, introduce the box of the adenotome under the soft palate by turning it sidewise, the child lying flat on its back. Now lift the instrument, raising the soft palate with it, and feel for the posterior end of the septum. When this is felt, with the shaft of the instrument midway between the upper and lower teeth, the instrument is pushed directly toward the occiput to engage the adenoids. The blade is now sent home, cutting through the mass of adenoid tissue in the box. This maneuver should be repeated twice, introducing the instrument to the median line in the same way and then sliding it laterally, first to one eustachian bulb and then the other, bringing away the adenoid tissue adhering to the lateral wall of the epipharynx. Now wrap a piece of gauze tightly around the index finger and introduce in under the soft palate, using a wiping motion upward to remove any small fragments of adenoid tissue that may have been left behind. Follow this with a wiping motion downward under each eustachian bulb. The advantages of the La Force box adenotome are twofold: *First*, the removal of the adenoids is more complete than with any other instrument; *second*, it is not possible to injure the mucous membrane of the posterior pharyngeal wall or traumatize the eustachian bulbs. The blade is so guarded that rough handling by inexperienced operators can do no damage. The use of the curette in removing adenoids is to be condemned, except in the most experienced hands. The removal is less complete, and the amount of traumatism to surrounding parts is much greater. Also, when the mass of adenoid tissue is caught in the box of the adenotome and removed by the surgeon he is not left in any doubt as to whether the adenoids have been removed. With a curette, if the bleeding is at all free, as it usually is, the operator is frequently in doubt as to the amount of adenoid tissue removed.

Treatment.—Once a purulent condition has established itself in the middle ear of a child, no time should be lost in making a wide opening through the drum membrane. This should be done under general anesthesia, unless the purulent condition has supervened on a severe lung involvement. In that case the physician in charge must judge whether the shock of the general anesthesia or the shock of opening the drum without anesthesia will be more injurious to the patient. The practice, in some clinics, of opening inflamed drums without anesthesia or under so-called local anesthesia is to

be severely condemned. No otologist who hopes to hold his patients would think of opening the eardrums of adults without an anesthetic, and if he did make such an attempt widely it would be wise for him to provide himself with a baseball mask or some other mode of protection. Simply because one is the larger, and the child has no choice in the matter, is no justification for inflicting pain on the child one would not be willing to bear one's self.

The choice of the anesthetic to be used must be left to the physician who is going to administer it, if he is at all experienced. Ethyl chloride in experienced hands—Gwathmey has now declared it safe (*New York Medical Journal*, June 19, 1920)—is an ideal anesthetic for these short operations. The patients go under quickly, remain under lightly, and come out quickly, and there is a minimum of post-anesthetic nausea. Also, there is less stimulation of the secretions than with almost any other anesthetic. However, all anesthetists are not agreed as to the element of safety in the administration of ethyl chloride. Until they do come to some agreement among themselves, there seems some reason to fear any anesthetic containing a chlorine radicle. These include chloroform, ethyl chloride, and somnoform, a combination of ethyl and methyl chloride. If an inexperienced anesthetist must be accepted, the following would seem to be a safe rule: In children under six months, a few drops of chloroform on a handkerchief, with careful watching and prepared to change to ether on the slightest indication. From six months to two years, ether is safe and the primary anesthetic stage gives ample time to do a double myringotomy, so that there is but little nausea in most cases. From two years up, when the respiratory muscles have sufficiently developed for rebreathing, nitrous oxide alone or combined with oxygen is a very satisfactory anesthetic. However, this requires more apparatus than is usually available.

The incision of the drum membrane should be begun by inserting the myringotomy knife deeply into the opening of the eustachian tube and carrying the incision up across the drum membrane in front of the handle of the malleus, and if much inflammation is present, out on the canal wall through the crucial ligament. The knife is then returned to the entrance of the eustachian tube (the experienced otologist quickly distinguishes this spot by the feel of the knife), and the second incision is carried downward, backward, and upward behind the handle of the malleus. This double incision forms a horseshoe-shaped flap of the drum, supported on the handle of the malleus, and is the form of incision most likely to remain open when the pressure behind the drum membrane has been relieved. This free opening relieves the pressure produced by the collection of pus and allows the pus to escape, rather than be forced into the mastoid antrum. It must be remembered also that the opening of the drum membrane is done for the purpose of conserving the hearing, as well as preventing mastoid infection, and the opening in the drum membrane must be kept open until a cure of the purulent condition has been effected.

Having established free drainage through the drum membrane, the treatment divides itself into two categories, that directed to the nasopharyngeal

space, whence the infection originates and the source from which it is maintained, and that directed toward the relief of the purulent condition in the middle ear itself. Babies and small children cannot be taught to gargle, and besides a gargle does not reach the spot that is maintaining the infection—the adenoids. For this reason I am accustomed to instruct the mother or nurse to place the child on its back and allow about a medicine dropper full of some antiseptic solution to flow through the nose into the post-nasal space. This should be done every two hours, at the same time the ear is irrigated. For this purpose there is nothing superior to Dobell's solution, or this may be diluted with an equal amount of physiological saline. It will also improve the action somewhat if enough adrenalin chloride is added to make a strength of 1-10,000. The alkali in Dobell's solution helps to dissolve the mucus from the nose and throat, the carbolic acid acts as an antiseptic and astringent, the adrenalin helps in contracting the tissues and improving the drainage; the whole hastens the return of the nose and throat to a condition of health—otherwise it cures the "cold." As the nasal discharge lessens it is sometimes advisable to substitute argyrol or some other astringent antiseptic for the Dobell's solution used in the nose. If the pharynx, including the tonsillar region, shows much inflammation, this treatment of the nose can be supplemented by swabbing the throat. This is conveniently done by wrapping a piece of gauze or other soft cloth about the finger and moistening it with Dobell's solution and swabbing the pharynx thoroughly.

Before the incision of the drum membrane, while the ear is under observation, the use of drops of any kind for the prevention of inflammation and pus in the middle ear or for the relief of pain is to be wholly condemned. This practice is quite analogous to the administration of morphine in a suspected case of appendicitis. The morphine does at least relieve pain. In the case of drops of phenol and glycerin, at best there is but a slight analgesic effect, and they alter the drum appearance to such an extent as to render an accurate judgment on inspection difficult. The various forms of hot applications in the canal, oil or water, have even less justification. These burn and blister the drum, or else render it water-soaked, to such an extent as to wholly mask the condition behind the drum on inspection, while they give no relief from the pain, and the burned, blistered drum even adds to the discomfort present. It is scarcely worth while to remark that there is no absorption of drugs from the skin of the external auditory canal and the outer layer of the drum membrane, and that if there were absorption its effect would not be exerted locally, but through the blood stream. If it is desirable to make some attempt to relieve pain before the incision of the drum membrane, the use of an ice-cap to the side of the head is rational and does not interfere with the diagnosis on inspection. Either the ice-cap or hot water bag may be used if it is desired to make an attempt to prevent the inflammation from advancing into the ear. The effect of either is very doubtful, as their nearest approach to the middle ear is a full inch or more from the seat of the inflammation.

If there is a free flow of pus from the middle ear after the incision of the drum, as there usually is, the external auditory canal should be irrigated with some antiseptic solution every two hours. If, at the time of making the incision in the drum membrane, no actual pus is demonstrated and the bleeding is slight, the beginning of the irrigations may be deferred till the next morning. This for the reason that if a drum is opened in which there is no infection in the middle ear, deferring irrigations will allow the drum to react and there will be less chance of introducing infection by the irrigation. On the other hand, if there is pus present in the middle ear at the time of making the incision, or if the bleeding is free, indicating an early stage of congestion and infection, then the irrigations should be instituted within the hour of making the incision. This will prevent the firm adherence of the blood clot over the line of incision, and thereby improve drainage. As children's skins are very tender and easily irritated, some antiseptic should be selected for the irrigation that is as slightly irritating to the skin as possible. For this purpose I am accustomed to prescribe boric acid, a teaspoonful in two glasses of lukewarm water. The mother or nurse should be instructed to pull the auricle outward, backward, and downward, to outward and backward, depending on the age of the child; to use a syringe the tip of which can be inserted deeply into the canal, and to use a slight amount of force. The syringing must be persisted in until the ear canal is free from collected pus. After the syringing is complete the canal should be carefully dried with a bit of cotton wound on a toothpick and insinuated into the canal to absorb any moisture present, and a few drops of some antiseptic solution placed in the ear. The following prescription answers the purpose very well, but is not ordered till the second or third day after the performance of the myringotomy:

Tincture iodine	gtt. xv.
Phenol, 95 per cent.....	gtt. xv.
Alcohol	5 ij.
Distilled water, qs. ad.....	3 j.

As the amount of discharge from the middle ear lessens, the intervals between the irrigations should be lengthened until the ear is irrigated three times a day. This number of irrigations should be continued until an inspection of the ear reveals a drum membrane so far restored to normal that the incision is healed and the landmarks restored.

If the skin becomes irritated and eczematous under the irrigations with water and the antiseptic drops long continued, it should be protected by applying some ointment with a vaseline base each time before the irrigations are to be carried out. Borated vaseline or boric ointment are as good for this purpose as anything else. The insufflation of dry powders into purulent ears is to be wholly condemned. They will, in too many instances, form hard cakes in the fundus of the canal, in this way interfering with the escape of pus, rather than retarding its formation. Unless the child is in the hospital or under the care of a very competent nurse with special ear training, I am of the opinion that gauze wicks placed in the ear are to be equally condemned. When a gauze wick is placed in the

canal in a case of acute purulent otitis media it should be changed at intervals of from four to six hours if the discharge is at all free. Otherwise the wick becomes foul and defeats the very purpose for which it was used—the rapid carrying away of the pus. The changing of a wick requires the most deft manipulations to prevent traumatism, thus giving the added risk of furuncle formation. But the real danger of using gauze wicks in the canal of a child is the failure on the part of the parents to carry out instructions. Each otologist sees cases in which a gauze wick has been placed in the canal in a case of purulent otitis media, and the patient has shown up in the office of another otologist or in a clinic days or weeks later, perhaps with a developed mastoiditis.

The time required to effect a cure varies widely with different patients, but perhaps between one and six weeks will be a safe limit as to time requirements. It is necessary, however, to fix mentally a definite time limit for the treatment of a case of acute purulent otitis media in a child. And beyond this the discharge must not be allowed to drag along. I am accustomed to place this time limit at between three and four weeks time, depending on the physical condition and progress of the individual patient. If at the end of this time the discharge does not give very definite indications of ceasing, it becomes necessary to consider more vigorous methods of treatment. The first of these is the removal of the adenoids. If the child is under two years of age, and if the tonsils are not particularly hypertrophied or infected, I am accustomed to remove only the adenoids at this time, leaving the tonsils until a later date. The pharynx seems to need the presence of the tonsillar mass for its proper development; also, the less that is done in an operative way at this time, the less recuperative load is thrown on the system of the child. It is surprising the rapidity with which a rebellious case of running ear will yield to treatment after removing the adenoids, even though they do not seem to be particularly bad.

If the adenoids are removed and the discharge threatens to become chronic, it becomes necessary to consider the advisability of performing a mastoid operation, even in the absence of positive symptoms of mastoid involvement. Under no consideration must an acute ear be allowed to become chronic. A healed mastoid wound with good hearing is preferable to a chronic running ear and the loss of hearing. If the infection has so far involved the antrum that the discharge does not yield to the usual forms of treatment, then the preservation of the hearing is so important as to justify this further step.

206 EAST SEVENTEENTH STREET.

A Possible Carrier of Encephalitis.—Lemierre relates the case of a man who recently developed the lethargic type of encephalitis. He was apparently infected from his daughter who had gone through the same malady nearly three years before. She had then been seen by Netter who had followed up the case during the interval. The girl herself escaped a second attack. On account of the presence of an epidemic it could not be so surely held that the girl was a carrier. The latter had apparently not wholly recovered from her original attack and on last September suffered a sort of recrudescence of some of her old nervous symptoms.—*Le Progrès Médical*.

A CONCEPT OF X-RAY PATHOLOGY.

VIII.—ODONTOPATHIES.

By A. J. PACINI, M.D.

WASHINGTON, D. C.

CHIEF OF LABORATORY AND X-RAY SECTION, HOSPITAL DIVISION,
U. S. PUBLIC HEALTH SERVICE.

To be conversant with the embryological development of the teeth is a desirable asset to the roentgenologist interested in the study of odontopathies generally; but the medical roentgenologist is more interested in dental pathology from the viewpoint of focal infection. First will be considered the x-ray anatomy of odontal structures in the adult.

There are five structures of immediate importance to the x-rayist. Successful x-ray technology demands that these structures be clearly revealed on the odontogram. It has been found a useful expedient to enlarge the odontogram through the use of the following technique: An Eastman Brownie No. 1 enlarging camera, or similar enlarging camera, is used in exactly the same manner that it would be used in preparing an enlargement of an ordinary photograph. The dental film is placed at the proper end of the enlarging camera. Instead of using print paper at the back end of the enlarging camera there is substituted a sheet of duplitzed x-ray film. Instructions for enlarging accompany the camera and are so elementary as to preclude any necessity for discussion at this point.

It is better to use duplitzed rather than single coated films for the reason that the duplitzed films are not only faster but furnish a slightly plastic effect that adds much to the perspective of the structures and in a great measure offers an adequate substitute for stereoscopy. The purpose of the enlargement is to secure clearer definition of the linear orientation of the maxillary and dental shadows. The enlarged film produced in the manner described above is no longer a "negative" but a positive; that is, opaque structures appear as dense shadows on the enlargement, contrary to the effect produced on the original dental film. When a print is prepared from an enlarged x-ray the opaque structures appear radiopaque in the print, as they are in the original x-ray film. The finished film or print, or the original odontogram if the enlargement is not made, should show: (1) Alveolaris. (2) Stratum durum. (3) Alveolodental membrane. (4) Cementum and dentin. (5) Pulp canal. These are diagrammatically represented in Fig. 17. The pulp canal is the central dark radiopaque tube; the cementum and dentin are radiopaque and are represented by the light area immediately surrounding the pulp canal. Investing the root of the entire tooth is a membranous tissue, the alveolodental membrane which serves the dual function of contributing to the nutriment of the tooth and to its support. It is radiopaque and shows as a dark area entirely surrounding the root. There is then a radiopaque or white strip of hard, compact bone that lines the alveolus. This is the stratum durum. Then comes the reticulated spongy or cancellous network known among roentgenologists as the alveolaris. (There is some objection to the term alveolaris in its use as a noun for the spongy portion of the mandible; but common usage in x-ray laboratories seems to determine the persistency of the word.)

Pulp Canal Pathology.—The pulp canal may be the site of an acute inflammation. Bacterial invasion of the cavity is followed usually by an accumulation of inflammatory products admixed with gaseous accumulation. The purulent material in an acute process is radiopaque; so that the normal radiolucency of the pulp canal assumes radiopacity in acute pulpitis. The gases of decomposition gradually accumulate, exerting increasing pressure as their volume augments. They are then expelled through the apical foramen or through a cavity in the crown of the tooth. Their intermittent collection and expulsion causes intermittent pressure to be exerted on the contained nerve and gives rise to the characteristic "jumping" toothache. Sometimes there accumulate in the pulp canal calcareous concretions called pulpoliths or pulp stones. They cause pain owing to the irritation by pressure on the nerve. They may occur in the canal or in the crown cavity. Their x-ray diagnosis is usually readily accomplished and consists in observing a radiopaque nodule in the radiolucent pulp canal stripe. It is seldom that cases of acute pulpitis are referred to

FIG. 17.—Diagrammatic representation of a tooth showing the central pulp canal in black, the cementum in white, the alveolodental membrane in black, the stratum durum in white, and the alveolaris in white and black.

the x-rayist. Acute pulpitis is of interest only in that it bears an etiological relation to alveolar abscess. When the infectious material is expelled through the apical foramen into the alveolodental membrane, this succulent tissue may become infected and give rise to the condition known as periodontitis.

Periodontitis.—A rapidly coursed infection may localize immediately in the vicinity of the apical foramen; but if more insidious it may spread laterally either along the distal or the mesial surface. As the infection spreads the alveolodental membrane loses its radiolucency and acquires radiopacity. When the etiology of the periodontitis is incident to a pulpitis, progress of infection in the alveolodental membrane is distinctly recognized as originating at the apical foramen and directed crownward; but if the infection is begun at the gum surface of the tooth, as in pyorrhea alveolaris, the course of infection in the alveolodental membrane is readily observed to progress from the crown toward

the apex. Generally, periodontitis of apical origin is localized, while the periodontitis of gum origin (pyorrhea alveolaris) attacks the entire membrane. The alveolodental membrane is elastic and while it serves as a support for the tooth it also shares the function of acting as a buffer. When the inflammatory products accumulate the pressure that they exert dislodge the tooth to the side opposite the infection. If the infection is apical the tooth is pushed forward out of its socket; if the infection is mesial the tooth is distorted distally, and, if the infection is distal the tooth is thrust to the mesial side. This can be recognized at once on the x-ray film. Normally the alveolodental membrane shows as a radiolucent stripe of equal width entirely surrounding the tooth. The part of the membrane involved in periodontal inflammation becomes radiopaque and its width is increased. So that periodontitis manifests, in x-ray pathology, as an increase in radiopacity and a distortion in alveolodental space between the affected and unaffected side.

The alveolodental inflammation may assume chronicity, when it invites osteoplastic deposit. The root of the tooth accumulates calcified strata. Continued periodontitis stimulates cementoblasts so that an exuberant addition of cementum accumulates on the root. When the addition proceeds at the expense of encroaching upon the alveolodental membrane, and the process is confined to the odontal side of the stratum durum, the lesion is called

Pericementitis.—Pericementitis is readily visualized on the x-ray film by the roughening and irregularity in the outline of the root. Cementoblastic proliferation may continue to an exaggerated amount, the root becoming tortuous and enlarged. As it expands it virtually eliminates the alveolodental membrane until it approximates the stratum durum. If the proliferation still continues it may crush the stratum durum and invade the alveolaris. The condition is known as

Hypercementosis.—The difference between periodontitis and hypercementosis is one of degree; but the x-ray pathology is important for the reason that in hypercementosis mechanical difficulties present in tooth extraction, the hypercementosed apex making for difficulty.

The alveolodental infection, instead of pursuing the chronic course and giving rise to periodontitis or hypercementosis, may remain acute. Acute products of suppuration are more osteolytic than the chronic products, and they exert their erosive action on that bony structure less able to defend itself immunologically. Immunological defense rests with nutritive proficiency. The cementum of the tooth is better nourished than the stratum durum of the socket; so that the stratum durum is first to suffer in erosion incident to pyogenic infection. When the pus is localized the stratum durum in the immediate vicinity is gradually dissolved until it is completely burrowed, the pus then entering the spongy alveolaris.

Alveolar Abscess.—When the stratum durum has been perforated and the pus has entered the alveolaris the condition is known as alveolar abscess.

The alveolodental membrane is delicate and is protected in part by the mantle of stratum durum that overlaps it. When the stratum durum is removed either by trauma or as the result of osteolytic

destruction, two important phenomena arise; first, in proportion to the amount of stratum durum divested, support of the tooth by the alveodental membrane is lost; and secondly, in proportion to the amount of alveodental membrane exposed, an area for supply of tooth nutriment is destroyed. In a great number of cases operatively controlled by careful dental surgical technology, it was determined that when an amount of stratum durum equivalent to the distal third of the root was divested, the impaired support and the loss of nutriment resulting was such as to preclude the possibility of operative interference (apicectomy) with the view to saving the tooth; but if one-third or less of the distal root area of stratum durum is divested, apicectomy should be tried with the hope that successful rescue of the tooth results. Success rests in proportion as less stratum durum is lost. From this it is clear that the x-ray identification of the stratum durum is useful for two cogent reasons. First, its continuity must be elicited and if broken, evidence is certain of an alveolar invasion; secondly, the extent of stratum durum destroyed must be determined for guiding the dentist in positively indicating the advisability to operate or not to operate.

A chronic abscess manifests the same x-ray pathology that does an acute abscess, that is, a break in the continuity of the stratum durum at some point and connected with this break a radioparent rotund shadow in the alveolaris. Whether acute or chronic, the important feature is the break in the continuity of the stratum durum for the diagnosis of abscess. It is imperative to observe that no area of alveolar radiopacity can be considered an alveolar abscess unless the immediately adjacent stratum durum is burrowed. This x-ray criterion serves as a means positive for the differentiation of artefacts, sinus shadows or foramen radiopacities oftentimes mistaken for abscess.

The term granuloma is used with a special meaning in odontopathy. It refers to an abscess encapsulated in a fibrous membrane. Its origin is in every way identical to that of the acute or chronic abscess from which it differs only in the fact that a fibrous capsule forms around the purulent accumulation. There is no absolute distinction, by means of x-ray signs, indicative of granuloma; nor is it desirable that there should be. Acute abscess, chronic abscess and granuloma all register as radiolucent areas with a loss in stratum durum and a loss in alveolar cancellations; and to the clinician all indicate a locus of infection of potential equality in their contribution to the pathogenesis of systemic disease.

Occasionally, the nidus of infectious organisms may be hematogenous, conveyed by the capillaries to the alveolaris in the region of the alveoli. The bacteria may become deposited and they may incite in-

flammation, the first stage of inflammation being that of hyperemia. In these cases the acutely inflamed alveolaris becomes engorged with blood and cellular infiltration so that the spongy meshes are filled with a material nearly as radiopaque as bone; and the alveolaris loses its x-ray characteristics of reticulation and assumes an evenly diffused area of radiopacity. The condition may simulate clinically an abscess and the patient referred for x-ray, when the odontogram will reveal the congested locus readily diagnosed hyperemia. All of the infectious conditions mentioned, pulpitis, periodontitis, pericementitis, hypercementosis, and alveolar abscess, are in reality various stages of the same condition. They represent different degrees of acuity or

FIG. 18.—Diagram illustrating the events in infectious odontopathies. The arrow indicating the progress of infection which may be diverted at any branch on either the acute or chronic side. The stratum durum is the threshold of focal infection.

chronicity and all tend to one goal, the production of the alveolar abscess. When the alveolar abscess is formed it becomes a focus of infection and may or may not be of extreme importance in the etiology, sometimes obscure, of systemic disorder. For clinical purposes, when the infection remains localized on the odontal aspect of the stratum durum, focal infection is practically overruled; but when it perforates the stratum durum and invades the alveolaris the locus may be potentially a source of danger. The nomenclature devised is simple and fulfills every need in truly expressing the stage of infection, in leading to an inference of the possibility of focal infection and in

guiding the operative dentist in selecting the method of election for inferring in any case. In general, radiolucency or radioparency point to acute infection; radiopacity points to chronic infection. The entire syndrome may be represented diagrammatically as in Figure 18.

The invading organism enters the pulp canal through a defect in the crown and incites an acute pulpitis in which the pulp canal radiolucency assumes radioparency; or the infection may become chronic and pulpolith form, when the progress is revealed as a radiopacity. Infection may progress and extend through the apical foramen into the alveolodental membrane, where, remaining acute it gives rise to the radioparent periodontitis, or if it becomes chronic may occasion radiopaque cementoblastic proliferation leading to pericementitis or hypercementosis depending upon the degree of proliferation. From the membrane infection may progress and attack the stratum durum, perforate and invade the alveolaris and form the alveolar abscess revealed by a radiolucency in which radiolucent area the cancellous structure of bone is wanting. Alveolar abscess may be acute or chronic, with or without a fibrous encapsulation, but in all cases is revealed by practically simple x -ray pathology. The infection may subside, the alveolar abscess gradually disappear and the infection retrace its course through the stratum durum through the alveolodental membrane out of the pulp canal. At any point in the progressive or retrogressive process of the infection, the process may stop and assume chronicity. In the diagrammatic representation the course of the inflammation is shown as a continuous line. At any stage in the course, there may be an aberrant deviation either to acuity or to chronicity, indicated by the arrowed branches.

The classification of infectious odontopathies thus presented is based upon a simple understanding of the pathology incident to the process; upon pathological changes incident to the various structures involved in the various steps of the infection; upon well-defined and easily recognized x -ray signs. The nomenclature used in describing the affections is simple, ample and comprehensive and makes for a standard that should be acceptable to all. Not only is there an efficiency gained clearly in eliciting the x -ray pathology, but certain surgical criteria are revealed with an accuracy that cannot be attained through any other avenue.

Pyorrhea Alveolaris.—In Riggs' disease the endameba buccalis has been thought to be the etiological factor, it having been found in great numbers in the purulent secretion that forms between the gums and the roots of the teeth. Whether due to the endameba or to some other cause the infection begins at the gum and invades at once the alveolodental membrane. It exerts an osteolytic action affecting first the stratum durum. In reality, the first lesion is a general periodontitis; and in its early stages it cannot be distinguished, by the x -ray, from a periodontitis of bacterial origin other than pyorrhea excepting for the fact that most usually pyorrhea affects the entire alveolodental membrane, whereas periodontitis of pulp canal origin is generally localized either at the apex or laterally in the membrane.

When the pyorrhea has existed for little time it

erodes with completeness the stratum durum before it attacks the cementum of the tooth; and after it has existed with any virulence, and the stratum durum has uniformly and entirely dissolved, then, and only then, the cementum of the tooth is attacked and becomes irregular in outline. This is an important x -ray criterion useful further to differentiate pyorrhea from other conditions. In pyorrhea the stratum durum is divested from entirely around the tooth and the tooth surface is roughened and irregular. No x -ray inference of pyorrhea should be given that does not clearly show a complete divestment of stratum durum.

Differential Diagnosis.—The importance properly to diagnose alveolar abscess makes it imperative that there be discussed conditions most likely misinterpreted in diagnosis.

The mental foramen in the lower jaw and usually located in the region of the apex of the second or first lower bicuspid may be mistaken for an abscess cavity; but if the stratum durum be traced around an uninfected tooth, it will be found continuous and the mistake absolutely precluded.

The anterior palatine foramen, occurring in the region of the apices and between the roots of the upper central incisors may sometimes be erroneously diagnosed an abscess cavity; but here again a tracing of the stratum durum will make for positive differentiation.

In the region of the upper bicuspid and molars, the various chambers of the antrum of Highmore may carelessly be considered abscesses; or, more frequently, the antrum is considered perforated because the root, usually buccal, of the molar is apparently projected into but really only photographically superimposed on the antrum shadow. When this apparent projection into the antrum is visualized, a tracing of the stratum durum around the root will clearly reveal that the case is one of superimposition and not one of antrum perforation.

The inferior dental canal running its course parallel to the mandibular ramus may inadvertently be regarded as a fistulous tract. It can be readily appreciated as non-pathological by the fact that it connects with the mental foramen, and the mental foramen is soon recognized as a physiological perforation and not as an abscess.

Impacted Molar.—The third molar may sometimes be impacted against the molar preceding it. The third molar may have its axis at right angles to the jaw or its axis may incline even as much as 90 degrees to the angle of the tooth in front of it. The diagnosis of impaction is made on the absolute proximity of the second and third molars. The clinical symptoms that may arise from an impacted molar are dependent upon two factors; first, the degree of impaction as determined by the proximity of the two teeth; and, secondly, by the determination of the presence of suppuration investing the impacted molar. Suppuration, generally accompanies impacted molars that lie in a horizontal plane. In these cases the pus accumulates under the inferior plane of the molar and soon burrows into the cancellous tissue of the jaw bone. An impacted molar should be radiographed from various angles in order to make certain that the impaction is not a photographic appearance resulting from the superimposition of distorted tooth shadows. If several odonto-

grams made at widely varying angles all show absolute proximity of a second and third molar, impaction is identified as certain.

Teeth other than molars may be impacted. These are readily identified on the odontogram.

Developmental Anomalies.—The *x*-rayist should be familiar with the general embryological knowledge incident to tooth development. In preparation for the development of the teeth, the tooth band is formed in each jaw following the line of the future alveolar ridge. The band is continuous from one end to the other and soon thrusts out ten buds which develop into enamel organs of the twenty deciduous teeth. As the enamel develops the connective tissue of the primitive jaw undergoes certain changes; the cells growing into its cavity becoming more highly specialized, and forming the dentin organ. The two are surrounded by the dental follicle. These two parts constitute the tooth germ and develop highly specialized cells which produce the various parts of a tooth—the enamel, the dentin and the alveolodental membrane. The permanent teeth are formed in a similar manner.

The teeth begin to calcify at about the fourth fetal month. The temporary teeth are completely calcified at the end of the second year, when the roots are fully formed and the apical foramina are established. It is to be remembered that the apical foramen of a young tooth flares; that this normal appearance should not be confused for the pathological widening sometimes seen in elder persons as a result of pulpitis and incipient apical abscess.

About the middle of the second month of fetal life bone formation starts in the jaw. Several centers of ossification appear and quickly unite, their contour establishing the primitive jaw at the end of this time. First forming an open gutter beneath the tooth follicles, the bone soon surrounds their lateral walls, finally inclosing each follicle in a separate compartment, the sides arching over and practically completely encapsulating the developing teeth. The condition is reached about seven or eight months

pairs, the central incisors first, then the laterals, then the molars. Next the cuspids usually appear and finally the second molars. It is customary for all the temporary teeth to be erupted by the end of the second year.

Temporary teeth are only a short time intact; and the process of decalcification, which begins about the fourth year at the apices of the central incisors, soon follows in order reverse to the process of eruption. This phase of decalcification is completed in about three years, when the remaining part of the tooth is cast off.

Of the permanent teeth, calcification begins in the sixth year molar, the other teeth following in sequence until all are fully calcified between the 18th and 20th years.

Formation of the permanent teeth takes place above and below the temporary ones. The crowns of the permanent teeth gradually force their way to the surface, erupting as first permanent molars about the sixth year. At about the age of twelve, the second permanent molars erupt. Normally the third molars should erupt between the eighteenth and twentieth years, but they may be retained causing unerupted third molar, frequently a source of trouble. At twenty years of age there should normally be thirty-two teeth entirely erupted, their roots fully formed; that is, dentition should be completed.

Thoma in his atlas of "Oral Roentgenology" gives the following table relative to the chronology of human dentition:

Chronology of Human Dentition. The approximate time of the beginning and completion of calcification, eruption, decalcification and loss of the teeth is given in the following table. Variations from these dates are, however, very common. As it is often of greatest importance to know the condition exactly in order to decide on the advisability of extracting or retaining a temporary tooth, to determine whether the root canals are completed, or to discover whether the apical foramen is widely open or closed, it is wise to diagnose the case by means of a Roentgenogram, which discloses the exact condition.

	Tooth	Time Calcification Begins	Time Calcification Completed	Time of Eruption	Time Decalcification Begins	Time Tooth Shed
Temporary Teeth	Central incisor	4th fetal month	17th-18th post-natal month	6th-8th post-natal month	4th year	7th year
	Lateral incisors	4th fetal month	14th-16th post-natal month	1st-9th post-natal month	3d year	8th year
	Cuspids	5th fetal month	24th post-natal month	17th-18th post-natal month	9th year	12th year
	1st molars	5th fetal month	18th-20th post-natal month	14th-15th post-natal month	6th-7th year	10th year
	2d molars	5th-6th fetal month	20th-22nd post-natal month	14th-24th post-natal month	7th-8th year	11th-12th year
Permanent Teeth	Central incisor	1st year	10th-11th year	7th-8th year		
	Lateral incisor	1st year	10th-11th year	7th-8th year		
	Cuspids	3d year	12th-13th year	12th-13th year		
	1st bicuspid	4th year	11th-12th year	10th-11th year		
	2d bicuspid	5th year	11th-12th year	11th-12th year		
	1st molar	8th fetal month	9th-16th year	6th-7th year		
	2d molar	5th year	17th-18th year	12th-14th year		
	3d molar	9th year	18th-20th year	17th-20th year		

The mandibular teeth precede those of the maxilla by short intervals.

after birth. As the advancing erupting teeth progress, simultaneous absorption of the bone begins. The temporary teeth erupt shortly after their crowns have been completed. As the crown advances the root progressively calcifies so that, in the great majority of instances, when the crown is fully erupted the root is at the same time fully calcified. The tooth having assumed its final position, it is held firmly in place by the support of the newly-formed alveolar process. Teeth generally erupt in

Irregularities of Tooth Eruption.—Teeth may be misplaced and found in any part of the maxilla or mandible such as the nasal cavity, the maxillary sinus or the lower borders of the mandible and ramus.

They may be unerupted or impacted. The *x*-ray study of impacted and unerupted teeth is important both as a diagnostic and as a determining criterion in pointing to the operation of election for interference. Unerupted and impacted teeth, perhaps be-

cause of the pressure which they frequently exert on the tissues toward which they are growing, may cause a reabsorption of soft parts and the lodging of an infectious nidus.

Partially erupted teeth are frequent observations; particularly so in the case with the wisdom or third molars. The x-ray shows exactly the mechanical defects and usually reveals associated infection.

Teeth may be congenitally absent, the absence involving their temporary or permanent structures, especially the third molars and the lateral incisors.

Supernumerous teeth are sometimes found, varying the mammalian formula. They are perhaps caused by epithelial remnants, parts of the tooth band forming a primitive enamel organ into which connective tissue papillae grow.

Tooth and Jaw Fractures.—Tooth fractures result from violence and are readily detected under x-ray examination. Fractures of the jaw will be more completely considered in a separate presentation.

Root Canal Fillings.—With the advent in dental surgery of root canal fillings, the x-rayist is burdened with the additional responsibility of guiding the operator in root canal filling. There is little difficulty in recognizing a canal filling, the gutta-percha or other material used for filling the cavity being radiopaque and easily distinguishable from the remaining tooth structure. The question of completeness in the matter of filling the canal is important. Properly to determine this the x-rayist must exercise every caution in producing minimum distortion. If this caution is not exercised a partially filled root canal may be reported as a completely filled one.

Secondary Complications.—A maxillary sinusitis or empyema of the antrum of Highmore is, in about 75 per cent of the cases, due to dental origin following as a sequel to all abscesses. This applies to acute and chronic sinusitis.

Pharyngitis sometimes occurs as a complication of abscesses involving impacted third molars. Impacted wisdom teeth sometimes occasion a tonic spasm of the muscles of mastication, a condition called trismus.

Ophthalmic disturbances may be secondary to oral conditions either through nervous irritation or as the result of hematogenous infection, iritis, cyclitis, choroiditis, retinitis and glaucoma (at times) being examples.

In a similar manner certain aural disturbances, preeminently otitis media and otalgia, may arise.

Various gastrointestinal affections have been traced to primary foci of infection of the mouth. Septic gastritis, septic enteritis, appendicitis and colitis, gastric and duodenal ulcers and gall-bladder diseases may sometimes stand in etiologic relation to primary foci of infection.

Affections of the heart, either of the muscle as myocarditis or of the valves as endocarditis are not infrequent sequels to primary infectious odontal foci.

Certain nervous manifestations have been traced to abnormal odontal conditions either because of mechanical impingement upon a nerve course or, as the result of perversion in nerve metabolism incident to infectious toxins derived from dental abscesses.

Various arthritides are in some cases associated with oral foci; and the different forms of infectious arthritides, of gouty arthritis, and atrophic and hypertrophic arthritis should incite a search of the odontal structures for the survey of the possible presence of infectious loci.

Since Billings redirected attention to the clinical entity of focal infection, and Rosenow advanced evidence tending to prove the transmutation of bacteria from avirulent to virulent capacities, much fervor has been wrought and unnecessary alarms sounded in the question of dental abscesses. There can be no doubt that oral foci of infection in many cases contribute, if they are not responsible for, to the etiologic pathogenesis of certain systemic disorders; but the x-rayist should not be accessory to a decision leading to the unrestricted extraction of teeth unless the x-ray evidence is absolutely indicative of the wisdom of the measure. The question has already been discussed under the title of alveolar abscesses and infectious odontopathies. It is reiterated here only in the trust that greater caution be exercised in advancing opinions relative to the potential harm incident to a focus of infection. In many cases the matter has been underrated; in equally numerous cases, it has been overrated. The x-rayist is in the position to strike a just balance between etiology and pathogenesis if he will examine infectious odontopathies with the scrutiny outlined under this heading.

SOME FALLACIES OF CHRISTIAN SCIENCE.

By GUSTAV F. BOEHME, JR., M.D.,

LOS ANGELES, CAL.

FORMERLY CONSULTING NEUROLOGIST, NEW YORK POLICE DEPARTMENT; ASSISTANT, EDUCATIONAL CLINIC, COLLEGE CITY OF NEW YORK; ASSISTANT PHYSICIAN, NEW YORK NEUROLOGICAL INSTITUTE; NEUROLOGIST, WEST SIDE HOSPITAL; ASSISTANT, VANDERBILT CLINIC, ETC.

BEFORE entering into a discussion of these problems, let me once and for all definitely define my position as to Christian Science.

Some years ago I felt that it offered a means of therapy, that in the blind faith and peculiar ecstatic state of mind that this so-called Science developed, there was a means of reaching a psychoneurotic at least. True it is that occasionally an individual seemed benefited thereby, but this was due entirely to the autosuggestive effects of the methods employed. Unfortunately, the average medical adviser has no patience with these high strung individuals, he or she is bromided, hyoscined, or what-not when his physician should rather delve into his mind with a knowledge of the social or other forms of psychology that medical schools do not teach. The result is that these individuals, illy adapted to life's real problems and unable to stand for themselves, reach out for an anchor, a haven of rest and the smooth, unctuous promises of Christian Science with its optimistic, business-like healers gain the upper hand to the detriment, not of the medical profession, as this deluded group would have us believe, but of the individual and his family. I unequivocally feel that the methods of this so-called church are, to say the least, criminal.

One attends their meetings and hears nothing but tales of miraculous cures, never of their failures or of their difficulties, and if one asks why

such and such a thing occurs, he receives the dogmatic (I feel like writing, dogged) reply, "They did not have sufficient faith. Their thought was wrong." Would that we Medicos might as easily escape from our failures—which we so gracefully admit, by the way—for can Christian Science offer us a Cabot, one Mayo, or one Osler, one healer who will classify his or her cases and admit their failures?

I stated a while ago that their methods were criminal. I believe that this is putting it too mildly. Let me cite instances from my own experience.

Case I.—I was, in my early practice, engaged to confine a woman, a Christian Scientist. When I arrived at her home, I found present a healer, a Christian Science nurse, a fanatic husband, and a woman who would have naught of medical aid. I was present only because the law required a trained accoucheur to sign the birth certificate. To say the least, I was interested, for I wanted to see what such a mental state could do toward ameliorating labor pains and facilitating labor. Let me picture the scene. The woman in bed reading a Christian Science pamphlet, the healer seated at the bedside reading aloud at times, the Christian Science nurse and the husband at the foot of the bed praying, while I, the physician, was not permitted to interfere—"The baby should come as God wished." Clinical results were as follows:

The woman moaned and groaned from pain. ("Just keep thinking of the Right," said the healer.) The labor itself was prolonged. ("If you would only keep your thoughts right," said the disciple of Mrs. Eddy.) The woman finally gave birth to a child, with a median perineal tear well into the rectum, which I was not permitted to repair. "For that tear is not a physical thing," said the scientific interloper. Sepsis set in three days later and finally the disciple of Æsculapius treated the case to a successful conclusion. A brilliant result, I suppose at some later Science meeting, for the tenets of Mrs. Mary Baker Eddy.

Case II.—I was called to attend a woman, age 60, whose husband promptly told me that his wife was dying from shortness of breath, but, "We are Christian Scientists—will you diagnose the case for us?" I found the woman with a marked cardionephritis, with the abdomen distended markedly by ascites. She could not lie down and breathe, despite her faith, and begged for relief. I did a paracentesis abdominis and removed eight quarts of fluid. Medical advice was proffered, but they would have none of it. Science would cure her. In one month I was called again. The patient presented the same picture as formerly. I again tapped the abdomen. I asked the patient why, if she had so much faith in Christian Science, the fluid re-formed. "Oh, well," was her reply, "I did not keep my thoughts pure or right enough. That is the reason." "But why have a physician remove the fluid?" was my next question. "Because," she stated, "this is a condition of bad faith, of the corporeal, so we use diseased methods to relieve until Love and Faith are triumphant." For a period of six months Christian Science imperfectly applied presented recrudescences of the fluid, while paracentesis abdominis, in its imperfect way, saved the patient from death by diaphragmatic pressure and cardiac failure. Ad interim, medication which would have been beneficial was refused. She then succumbed from cardiac dilatation and general anasarca—a triumph, I am sure, for Christian Science, for her faith had brought her back to the "Great Mind" that Mrs. Eddy calls God.

Case III.—This case well illustrates how convenient "pain" even though it "does not exist" can be even to the ardent Christian Scientist, and how "masses" may develop even though there is no "corporeal" disease when that filthy, material substance, money, is at stake.

I was called to examine a man said to have been injured in an automobile accident, six months after the occurrence, who said that he suffered from dizziness and pain in the head and that a tumor had developed over his right eye, all said to be due to his injury, and de-

manded "remuneration for his pain and sufferings," and yet he had been for six years "a student of Christian Science." I wondered when he would graduate or perhaps the presence of the cash remuneration was to be his diploma, for surely then "all pain and anguish" would vanish, due, of course, to his perfectly developed "faith."

Case IV.—A man had seriously smashed and lacerated his index finger. So much so that one of my associates deemed it necessary to do a partial amputation, but the patient would have none of it, until his practitioner had been called. It was decided that it would be wisest at least to sew up the wound, and an anesthetic was advised. But, no, the Scientist "would stand the treatment. There was no pain." My associate being of a practical turn of mind and not given to discussion agreed to do this. With the first needle prick, the patient gave a scream of pain and suffered so that the practitioner then requested him to take gas, "so that your hand will remain still while the surgeon sews it up." Notice the diplomacy of the healer. No mention of pain—probably the gas administered was part of the vaporous spiritual thought that transcends pain, that Mrs. Eddy speaks of. At any rate, it worked. Surely, a brilliant demonstration of the non-existence of the corporeal and of the pains of the body.

Case V.—This case will exemplify one of the most serious dangers to which Christian Science exposes both the individual and the community. I was requested by a Christian Science friend of mine to "take a look at my baby," a charming youngster of four years, of whom I was very fond. The youngster had a very evident measles. Feeling that I did not want to incur my friend's ill-feeling, I told him the condition of things and explained to him the dangers of pneumonia, ear disease, etc., to his child and also of his duty to his neighbors. "Keep the child warm and isolated and maintain his general hygiene" was my advice, "and if you want a healer call him in," for I believed after all that the practitioner could do no harm, but I was to learn a bitter lesson. The healer ridiculed the idea of the measles and ordered the child to play in the streets and declared that prayer would cure the little patient. The clinical results were as follows:

The child developed lobar pneumonia and empyema and died, the end result of improper care and exposure. Two neighbor children and a cousin that visited the family developed measles.

Was this case and its after effects ever quoted in a reading room meeting, or was the poor child and its infected neighbors guilty of wrong thoughts and a breach of Love, or did the Scientist healers believe that it would be wisest literally to obey the command of The Christ, "Suffer little children to come unto Me," and believe that death from a "non-existent process" would be the best way to consummate His command?

The following is the story of the end results of Christian Science in an interesting family. Dr. B. married Dr. F., and both built up a splendid surgical practice. Mrs. B., formerly Dr. F., later became interested in spiritualistic and so-called psychical research and finally joined the Christian Science Church. Gradually her interests became fanatical and she interfered with her own husband's practice by discussing problems with his patients and insulting their inherent intelligence. She became a very successful healer herself; her children, a wonderful boy and girl, were brought up to all the tenets of the new faith. The husband, in desperation, joined his wife's church to find familial peace if he could. My Science friends here have a wonderful proof (?) of the potency of Mrs. Eddy's doctrines; wonderful examples of the fact that "even doctors leave their work to enter our creed," . . . but, and here let me describe the end results. The wife plied her profession as a

healer and made a fair amount of money, until she developed kidney and heart disease at 52 years of age. As a friend of theirs since my childhood, I was called in to see her for diagnosis only. She gradually went down hill and in two years died of dropsy and cardiac dilatation. The daughter at 16 years developed tuberculosis and died in one year, primarily because no medical aid was sought until too late.

The father, broken in health and wealth, came to me one day and exclaimed, when I mentioned Science, "Don't ever bring that accursed name into my house, it has ruined our home and my life." I shall make no further comments on these poor people. Probably the intelligent reader will draw his own conclusions.

Cases could be multiplied to hundreds in my own personal knowledge. Neglected tuberculosis, mistreated cancer, pus conditions in appendix, gallstones, with consequent death, because surgical interference was not instituted until too late, come under the scope of dangers that this so-called Science reflects upon the ill, or shall we say, to appease our friends' desires, those whose thoughts have been so wrong, so non-loving, that evil gained the upper hand? Granting them even the latter statement, does it not seem logical, if diseased (?) medical methods, corporeal treatment, etc., does save lives and the health of these unfortunates, that perhaps these methods may even be God-given?

Mrs. Eddy, in her "Science and Health" makes much of the book of Genesis, and gives us her own poetic interpretation of that book. Of course, the God, the Master Mind, made it possible only for her and her pupils to understand, yet I would humbly suggest that perhaps the poor benighted doctor may have some God-given interpretation also. For example, Genesis states that the Lord created all things and had made all things subservient unto man. These things, our Scientist friends would probably sum up into nice lamb chops, well-broiled steaks, vegetables, edible crustaceans, anything that will keep their corporeal "mind" in good condition, nourishing it when it is well. For some strange reason, however, they cannot accept the digitalis plant for heart disease, yet they have no objections to the tea plant's stimulating qualities. They use clay to work in, but cannot see its value in infection; the earth may produce the gold to purchase the wherewithal—yes, and even pay for the practitioner—yet mercury, iron, and other beneficent metals are withheld in process of disease.

It seems to the doctor that when the wonderful Mind was conceived; that when this wonderful Mind called upon all subminds to be subservient, that in some way or other, he wished us to find and use the drugs that are provided by nature (a part of the Great Mind, by the way, according to Mrs. Eddy) to restore us to health.

If one seeks for the mystical and looks for the hand of God, can our Science friends point to a more appropriate story than that of the discovery of quinine? An Indian chieftain in Mexico, so the legend goes, had developed ague and so serious was his condition that, according to the tribal customs, he was driven into the forest to die. Taking with him his dog, he wandered into a morass. Sud-

denly he saw his dog eat of the bark of a tree. Being tired and sick and hungry, and reasoning that if the bark of the tree was good for his canine companion it might be edible for man, he ate thereof. Bitter it was, but what magic had occurred the next day! There was no chill, no fever. For some time he ate daily of the bark and waxed in strength and health and was able to return to his tribe a well man. That is how cinchona or quinine was discovered. Surely an act of God, if one believes in folk lore at all, and would Science have us believe that His gentle hand that pointed to this drug through the agency of one of his lower animals (or "minds") was directed in a way harmful to man?

And so it would be possible to point out, using Biblical authority and interpretation, that the physician after all has his part to play in life—that we are but "Servants of the God—the Great Mind," whatever you choose to call the "Infinite."

Nor do the criticisms of Christian Science cease here. Often the view is expressed that it is good for vacillating, nervous minds, and that it brings relief where physical methods fail. For some time I was disposed to believe this so, but continued observations fail to prove it true; that in fact Eddyism is the *cause* frequently of the development of psychopathic states in normal individuals.

The patient with a neurosis needs, not an artificial state of mind as created by Science, to combat his troubles, but a true understanding of the mechanism of his psychic state. Here the physician should be the guide. All toxic and other processes should be examined for and treated. Social and other difficulties should be investigated and corrected. Psychoanalysis and other methods should be employed to delve into the background of the patient's mind. In other words, the true way to correct neurotic manifestations is to show to the patient his norm—to explain to him, to have him understand clearly the "why and wherefore" of his condition—then there is a *true* solution for his difficulties, not a neural anodyne as Christian Science would be—leaving the psychic struggles unsolved and ready to react against the patient under new stresses and strains. It is the old picture, corresponding in physical diseases to the practitioner who heals by a true knowledge of pathogenesis and handles his knowledge intelligently to cure his patient with the physician who treats symptoms . . . and relieves them, but leaves the causative factor to continue its damages.

This paper has been the result of continual investigation of Christian Science . . . Mrs. Eddy's and her co-workers' literature has been studied, patients under their care have been observed; patients have been referred to them for treatment. I have personally known a group of healers intimately and studied their methods, and have for a period of time lived in the homes of Scientists. I have tried to keep an unbiased mind, but as time progressed and I was able to evaluate their methods and their end results, I am firmly convinced that it is a system that is noxious to everything—the individual, the community, and the State; it is a disseminator of contagious diseases; it withholds necessary treatment from deluded patients; it en-

dangers the lives of individuals ill from surgical conditions . . . and offers nothing in return but "Blind Faith," so blind in fact that recently, when in discussion with a friend who for eight years has professed Science, who has studied it regularly, and has as his closest friends many well known healers, I drew him to a logical conclusion in regard to disease—he stammered and then blindly replied: "I can't answer you, but there are some who can." Never, except in the Middle Ages, was Faith so blind—when an individual is willing to submerge his own ability to reason and accept the thoughts of another absolutely.

I have attempted here to point out certain dangers involved in the tenets of this cult. I have cited specific cases (any of which I shall be glad to corroborate), in the hope that perhaps a citation of facts will help somewhat to batter down the walls of that citadel of Ignorance and Blind Faith—"Christian Science."

ROOM 234, CONSOLIDATED REALTY BUILDING.

HYDROCELE IN CHILDREN.

By MAXWELL QUACKENBOS, M.D., M.R.C.S. (Eng.).

L.R.C.P. (Lond.)

NEW YORK.

In the seventh month of fetal development the testis is situated in the small peritoneal fossa at the internal abdominal ring. The descent and inguinal invasion of the testis within its peritoneal investiture, the processus vaginalis, occurs during the eighth month to reach the normal scrotal location at term, at which time that part of the former peritoneal sac in relation to the spermatic cord, the funicular process, is obliterated along its inguinal course of a quarter of an inch, while the distal portion of the covering remains patent to form the tunica vaginalis of the testicle.

A variety of anomalies may result from the delayed or imperfect fusion of the processus vaginalis. Increased intraabdominal pressure from muscular effort, as crying or straining, is the essential factor in the clinical manifestation of the congenital defect. Persistence of the fetal state, that is patency of the funicular process, if sufficiently large in caliber to admit gut or omentum, leads to a vaginal type of oblique inguinal hernia, whereas a small aperture may result in the production of a congenital or intermittent hydrocele due to the gradual ebb and flow of the serous peritoneal fluid. In passing it will be recalled that this, a hydrocele of a potential hernial sac, is not reducible by taxis.

In the female the peritoneal tube is termed the canal of Nuck, and faulty closure according to degree may likewise lead to a hernia or an encysted hydrocele of the round ligament. The inherent tendency of the anatomical defect to approach the normal and eradicate the developmental error is well illustrated by the fibrous ring occasionally observed at operation within the sac of long standing adult herniae. A similar condition occurs when the congenital hydrocele is converted into the infantile variety by the fusion of the funicular process at its upper end, severing the peritoneal communication. Closure of the lower end of the funicular process at the point of junction with the tunica vaginalis

results in the funicular type of hydrocele or oblique inguinal hernia, the latter constituting 95 per cent. of all congenital hernia (H. J. Stiles). When the patent funicular process is effaced at each extremity a hydrocele of the cord may make its appearance. The simple types of hydrocele delineated can by virtue of their several complications inculcate deference in the attempt of their radical cure.

Exception is taken to the misnomer congenital, meaning present at birth, as applied to hydrocele, a collection of (serous) fluid of the coverings of the cord and the testicle. The clinical recognition of the defect and its attendant swelling is not noted until the infant is several months old, frequently many months old. Post-mortem examination of infants shows the peritoneal cavity singularly free from serous fluid. The hydrocele in my observation is almost invariably present on the right side, although the anatomical defect is usually bilateral, present in both inguinal regions. The descriptive term, intermittent, is preferable to depict the occurrence of a hydrocele associated with a patent processus vaginalis.

That patency of the processus vaginalis, excluding the fetal condition, may remain latent until adolescence (or for an indefinite period) is shown by the incidence of the encysted hydrocele of the round ligament not uncommonly seen at this age, or the occurrence of a primary hydrocele of the cord following some profound muscular exertion. (R. Johnston, *Brit. Journal of Surgery*, viii, 29. Any collection of serous exudate, as a rule, is endogenous, secondary to some morbid process. Given the presence of the structural defect as discussed, in a young individual, accompanied by straining, is there a discernible causative factor in these cases of primary hydrocele? While it is exceedingly difficult to attribute any cause which in all instances would make one regard hydrocele as a symptom, still it is a more or less well known fact that hydrocele occurring in children is occasionally symptomatic of a subacute or chronic infective process. I believe that the situation of the focal lesion is to be found in the mesentery of the caput or its vermiform appendix in the majority of cases; I mention from my experience two cases in infants where the subsera of the processus vaginalis was studded with tubercles and three others where enlarged mesenteric glands were palpable under anesthesia, the peritoneal process however being healthy. Such infants may be breast fed. On analogy infantile hydrocele, or that of the round ligament or the cord would appear to be similar to a tuberculous hydrosalpinx. In the infantile type of hydrocele puncture of the sac by a trocar and withdrawing of the fluid generally effects a cure. In one patient, a boy of five years, the hydrocele repeatedly recurred after aspiration, and when I opened the sac a piece of detached omentum was found stuck on to the wall of it. In older children less frequently than tubercle, rheumatism may be the cause of the localized chronic peritonitis, and I have seen a funicular variety of hydrocele apparently cured by enucleation of the faecal tonsils. I am convinced that hydrocele in children should be regarded as a symptom of a localized subacute or chronic peritonitis unless actually proven otherwise, for in many instances the surgical cure of the hydrocele

is only remotely associated with the general and ultimate welfare of the patient.

Not all cases of hydrocele require operation, *i. e.* excision of the distended peritoneal process by the inguinal route. Inspection of the throat and for palpable enlargement of the afferent tonsillar lymph nodes, or examination in a warm bath for mesenteric glands may indicate the treatment to be followed. An inguinal truss or pad and bandage (in conjunction with local applications of tincture of iodine) sometimes leads to a cure. Phymosis is remedied and the minute preputial orifice if present corrected by meatomy according to the method of T. H. Kellogg. This consists in preventing the union of the cut areas by the introduction of a suture of double horse hair through the base of the incision, the knot of which is located in the wound. The tightly tied suture cuts out in five or six days. I have found it far more efficacious than the usual lubricated plug.

Medicolegal Notes.

Remaining Within the House—Meaning Under Insurance Policy.—The Arkansas Supreme Court holds that under a health policy providing for benefits if the insured should be compelled by disease to "remain continuously and strictly within the house" under the treatment of a regular physician, the fact that the insured took air and exercise under the direction of his physician would not preclude recovery; but the insured could not recover under the terms of the policy if the disease was one which required him to remain outside of the house rather than within it.—*Inter-State Business Men's Acc. Assn. v. Sanderson* (Ark.) 222 S. W. 51.

Misrepresentations of Applicant for Insurance as to Indigestion.—Section 639 Kentucky statutes provides that all statements in an application for insurance shall be deemed representations and not warranties, and, unless material or fraudulent, shall not prevent recovery on the policy. An applicant for a certificate of insurance in a benefit society, with knowledge that he was subject to indigestion, or had symptoms of serious disturbance in his digestive system, stated he had never had diseases or symptoms of colic, gallstones or indigestion, or other diseases of the digestive system. The Kentucky Court of Appeals, after examining in detail the evidence of several attending physicians and medical examiners for insurance companies, on the subject of the materiality of such diseases to the risk, held that the insured's widow could not recover.—*Sovereign Camp v. Thomas* (Ky.) 222 S. W. 69.

Physician May Disclose Information Received from Patient to Prevent Spread of Contagious Disease.—A novel case has recently been decided by the Supreme Court of Nebraska. Neither court nor counsel had been able to find any prior cases bearing directly on the question. A guest in a small hotel consulted a practicing physician, who informed him he believed his disease to be syphilis, and who later warned the proprietor of the hotel against the danger of contagion, so that the guest was forced to leave. He sued the physician for damages for alleged breach of duty arising from confidential relationship between physician and patient. The statute as to the disclosure of confidential communications to the witness stand did not, of course, apply to the case. There is, however, another provision of the Nebraska statute that a license may be revoked for unprofessional or dishonorable conduct, and among the acts of such misconduct, defined by the statute, is the "betrayal of a professional secret to the detriment of a patient."

By this statute, the court holds, a positive duty is imposed upon the physician, both for the benefit and advantage of the patient as well as in the interest of general public policy. It is often necessary for the patient to give information about himself which would be most embarrassing or harmful to him if given general circulation. This information the physician is

bound, not only upon his own professional honor and the ethics of his high profession, to keep secret, but by reason of the affirmative mandate of the statute itself. A wrongful breach of such confidence, and a betrayal of such trust, would give rise to a civil action for the damages naturally following from such wrong. But the doctor's duty does not necessarily end with the patient, for, on the other hand, the malady of his patient may be such that a duty may be owing to the public and, in some cases, to other particular individuals. Recognition of this fact is given by the Nebraska statutes, which delegate power to the state board of health and to municipalities generally, to require reports of, and provide rules of quarantine for, diseases which are contagious and dangerous. An ordinance in Omaha enacted under such power, providing quarantine of communicable venereal diseases, has been sustained by the Nebraska Supreme Court in *Brown v. Manning*, 103 Neb. 540, 172 N. W. 522. The court holds that the word "betrayal" in the statute quoted is used to signify a wrongful disclosure of a professional secret in violation of the trust imposed by the patient. No patient can expect that if his malady is found to be of a dangerously contagious nature he can still require it to be kept secret from those to whom, if there was no disclosure, such disease would be transmitted. The information given to a physician by his patient, though confidential, must be given and received subject to the qualification that if the patient's disease is found to be of a dangerous and so highly contagious or infectious nature that it will necessarily be transmitted to others unless the danger of contagion is disclosed to them, then the physician should, in that event, if no other means of protection be possible, be privileged to make so much of a disclosure to such persons as is necessary to prevent the spread of the disease. A disclosure in such cases would, it follows, not be a betrayal of the patient's confidence, since the patient must know, when he imparts the information or subjects himself to the examination that, in the exception stated, his disease may be disclosed. In order that such a privilege of making a disclosure be available to a physician, however, he must have had ordinary skill and learning of a physician, and must have exercised ordinary diligence and care in making his diagnosis; otherwise he could be subjected to an action for negligence in making a wrongful report. *Harriott v. Plimpton*, 166 Mass. 585, 44 N. E. 992. In making such disclosure a physician must also be governed by the rules as to qualified privileged communications in slander and libel cases. He must prove that a disclosure was necessary to prevent spread of disease, that the communication was to one who, it was reasonable to suppose, might otherwise be exposed, and that he himself acted in entire good faith, with reasonable grounds for his diagnosis and without malice. It appearing to the court that the facts disclosed by the record in the case showed that the occasion was privileged, that the defendant had reasonable grounds for his belief, that he made no further disclosure than was reasonably necessary under the circumstances, and that he acted in good faith and without malice, judgment for the defendant was affirmed.—*Simonsen v. Swenson*, (Neb.) 177 N. W. 831.

Notice of Disease to Medical Examiner is Notice to Insurer.—The Texas Court of Civil Appeals holds that where a medical examiner of a benefit insurance society was notified that the applicant for insurance had suffered from influenza, and this fact was noted in the report he made to the body having general authority over fraternal insurance, the insurance society was charged with knowledge of that fact and could not rely on the applicant's statement that he had not suffered from disease, under the rule that, although the answers of the insured may be untrue and incomplete, and this fact under the contract would avoid it, the insurer may by its conduct, or that of its officers, be held to have waived its right, and be estopped from having the policy declared void for misrepresentation or breach of warranty. While the Texas statute (Rev. St. 1911 art. 4847) permits contracts against waivers by subordinate bodies and their officers, there is no such law as to general officers or agents, and no provision in the constitution of the society against waiver by general officers would have any basis in law.—*Sovereign Camp, Woodmen of the World, v. Nash* (Tex.) 220 S. W. 235.

MEDICAL RECORD.

New York, March 5, 1921.

THE WORKING TOGETHER OF DENTISTRY AND MEDICINE.

WE recently referred to the growing art of chiropody or podiatry, and suggested that it would be the part of wisdom to absorb that as a medical specialty, teaching it in the curriculum of the medical school. If that is not done we shall before long find podiatry as a fully developed branch of the healing art with schools of its own and with educated practitioners demanding recognition as healers and relievers of human suffering. This mistake of aloofness or assumed superiority was made when dentistry began to acquire a standing as a branch of therapeutics, with the result that the two professions have long existed side by side, semi-antagonistic, and mutually ignorant of each other's teaching.

It is only recently that the inconvenience of this quality in surgical and medical practice has begun to enter the minds of practitioners of both the professions, and in consequence there has been a mutual drawing together of the leaders in these two branches of the healing art. The recognition of root abscesses and Riggs' disease as foci of infection bearing upon distant organs and even the brain, has served to show the mutual dependence of the two professions, but it was during the late war that the recognition of dentistry as a potential or actual branch of surgery was effected, this being forced upon the Army Medical Department by the brilliant reconstructive work of the members of the Dental Reserve Corps. There will still be accidents calling for skilled work of this nature, but it is along the line of preventive medicine and hygiene that the cooperation of dentist and physician will produce its greatest results. The public must be instructed in mouth hygiene, which is inseparable from general hygiene, and for this work reciprocal action of members of both professions on the platform and in the press is needed to feed the public appetite for knowledge of how to care for the body.

In many other ways the dentist and the physician could work together to mutual advantage, and as a beginning an "exchange of pulpits" would greatly promote the desired rapprochement. It is seldom that a dentist reads a paper before a medical society

and a physician speaking before a dental society is a still more rare object. This is not as it should be, for practitioners in either profession have much to learn from those in the other, and preventive medicine as well as therapeutics would profit greatly by this mutual instruction. The MEDICAL RECORD has from time to time published papers of great practical value written by dental surgeons, and the medical press generally would no doubt welcome other such contributions.

But the hygienic welfare of the community would be promoted by a still closer drawing together or indeed an amalgamation of the two professions. The holder of a medical degree could obtain the D.D.S. by a two year post-graduate course in a dental college. He might not in that time acquire a great degree of mechanical efficiency, but his new knowledge would render him proficient in the line of preventive dentistry. The comparatively new field of dental hygiene offers great possibilities for good to the right men. There are upward of 140 registered dental hygienists in the 1920-21 official list just issued for New York, and there is room for many more. These dental hygienists are an important factor in the scheme of prevention. Some are working in dental offices, others are engaged in public medicine. The Presbyterian Hospital is, we understand, the first hospital in this city to undertake this prophylactic work, and it has two men of this class, graduates of Columbia University, on its staff. We look to see this oral hygiene movement extend to the large commercial and manufacturing concerns in the country and be adopted as a recognized branch of industrial medicine. It would extend much more rapidly and surely could the two professions of dentistry and medicine be brought together as one strong body working as a unit in the field of preventive hygiene and therapeutics.

THE PHYSIOPATHOLOGY OF UROBILINURIA.

IN the physiological state the bile pigments thrown into the intestine are completely reduced to urobilin. This urobilin of intestinal origin has been given the name of stercobilin, but from the chemical viewpoint they represent a single product. Absorbed by the intestinal mucosa, this urobilin is carried to the cells of the portal zone and there utilized for the production of normal bile pigments. The latter are taken up by the cells of the suprahepatic zone and afterwards are thrown into the biliary ducts and then into the intestine. Consequently, the cycle of intestinal urobilin derived from bilirubin is perfectly continuous and regulated.

Besides the urobilin derived from bile pigment another urobilin is derived from hemoglobin. The red blood corpuscles are incessantly renewed, but many of them, escaping the hemolyzing action of the spleen, become hemolyzed in the blood plasma. This intravascular hemolysis—which continues the splenic hemolysis—is a physiological phenomenon, bringing about an incessant liberation of a quantity

of hemoglobin in the blood in direct relation to the intensity of the hemolysis, and therefore very small in normal conditions. This hemoglobin immediately undergoes the reducing action of the plasma which degrades it successively into all the derivatives up to the final term of urobilin and the urobilinoids. Carried to the kidneys for elimination, these urobilinoids and urobilin undergo another reducing action belonging to the renal parenchyma and there transform into urobilinogen. Such is the origin of the urobilinogen whose presence in the urine is perfectly normal.

The duality of the origin of urobilin—intestinal and intravascular—readily indicates the pathological circumstances in which urobilin is susceptible of appearing in the urine. The first is when the liver only imperfectly fulfills its function of arresting intestinal urobilin, either because this product reaches the liver in too large amounts—disturbances of the intestinobiliary functions—or because the indoplectic power of the hepatic cells is decreased from hepatic insufficiency. This is also the case when the amount of urobilin formed in the blood is so excessive that it cannot be reduced by the renal parenchyma, the intravascular hemolysis being exaggerated, so that only a portion of urobilin is transformed into urobilinogen while the excess passes without being transformed.

Finally, when dyshepatia exists a certain quantity of bile pigment is diverted to the blood, but in these circumstances two different conditions are to be distinguished: either the amount of pigment introduced into the circulation is very small, in which case the reducing action of the plasma may act on a portion of this bilirubin, transforming it into urobilin; or the quantity of pigment circulating is so great that this reductive action becomes exhausted in the early phase of degradation of the bilirubin without transforming the slightest amount into urobilin. In the first case, which corresponds to mild icteric states, there is urobilinuria; in the second case—which corresponds to the period of full development of icterus—there is no urobilinuria.

The simple application of chemical laws explains why urobilinuria is present at the commencement and end of icterus, but is absent during the height of the process. Thus urobilin may form in very different conditions, while urobilinuria will develop in all pathological states arising from a functional insufficiency of the liver, a disturbance of intravascular hemolysis, intestinobiliary disturbances, and icterogenous dyshepatia. In these conditions, when urobilinuria is present, the question to be solved is its origin. The first research to be made is that of the bile pigments in the blood, the only criterion of biliary icterus, and if the result be positive the urobilinuria is evidently related to a mild cholemia whose origin must be discovered and which is usually related to an icterus at its onset or decline. The urobilinuria is then the urinological symptom of a dyshepatia usually accompanied by hyperhepatia, that is to say, an entirely different condition and one that is almost the opposite to that of hepatic insufficiency.

The search for bile pigment in the blood being negative, indicanuria should be looked for, and if present the process is a hemapheic icterus, hemapheic being merely a mixture of indican and urobilin, as Dufau has demonstrated beyond doubt. In this case, the urobilinuria is symptomatic either of a disturbance of the intestinobiliary flux that other symptoms will render evident, or of an indoplectic insufficiency of the liver. It is only in the latter case that the urobilin can be said to be the pigment of a diseased liver and that hepatic insufficiency really exists.

Finally, if urobilinuria is not accompanied by either cholemia or indicanuria, the case is then a true urobilinic icterus, that is to say, whose coloring matter is not bilirubin but in reality all the urobilinoids derived from it. This true urobilinic icterus is met with in two circumstances. In the first place, when the quantity of hepatic bilirubin—which is the origin—is so minute that it is transformed into urobilinoids as soon as it is diverted to the blood, and secondly, when disturbances of intravascular hemolysis exist.

Now, the latter disturbances are met with not only in hemolytic icterus in the true sense of the term, but likewise in a large number of hemolyzing affections, and this is why it is not uncommon to encounter urobilinuria without cholemia or indicanuria in acute or chronic processes such as scarlet fever, appendicitis, typhoid, malaria, various types of intoxications, etc. Therefore, it is only after eliminating each of these processes that true hemolytic icterus can be considered, the diagnosis of which will be established by blood analysis.

It has been said that urobilinuria might develop during slow absorption of collections of blood. Unquestionably, bile pigment and urobilin are to be found in the fluid of old blood collections, but it is yet to be shown that this local urobiligenia can bring about urobilinuria. The notable diffusibility of urobilin should indicate the contrary.

As to the relations which might exist between urobilinuria and the presence of bile salts in the urine, it seems hardly possible to determine them precisely so long as the presence of these salts can be detected only by a reagent as indirect and uncertain as Hay's reaction. Nevertheless, it is more than likely that urobilinuria and cholemia are not necessarily subordinated to each other, and that in all cases Hay's reaction must not be accepted as a criterion of the biliary or hemolytic origin of an icterus.

SALTS OF RARE EARTHS IN TUBERCULOSIS.

FOR over a year Grenet and Drouin have been using salts of cerium in the treatment of tuberculosis and their report was recently given out at the Brussels Medical Congress. Mirande in the *Journal de médecine et de chirurgie pratiques* for October 10, 1920, xci, 19, gives a review of the paper and also of some activities by Lumière, Chevrotier, and Renon along similar lines. Frouin has been at work since 1912 on the behavior of tubercle bacilli in the presence

of these substances. He began with cerium and at first studied it in relationship with bacteria of various kinds. He then took up lanthanum and finally neodymium and praseodymium. The sulphates of the latter metals in a concentration of 1-1000 hindered the development of cultures of the tubercle bacillus. Injections of these various salts tested produced an intense leucocytosis. Lumière and Chevrotier studied the action of cerium salts on the growth of the tubercle bacillus and Renon seems to have made only clinical studies of the salts.

The metals tested all belong to the so-called cerium group, including samarium, neodymium, praseodymium, etc. Hence the author uses an expression, "ceric medication," to cover the entire subject. The sulphates of this group appear to be the best salts for clinical study. Thus far there seems little to choose between them, and they have been used also in combination. In the clinic the concentration of the solutions has been 2 per cent. and the intravenous dose 2 to 5 cgm. (the salts are not used in any other route). Twenty daily injections are followed by an equal number of days of rest.

The lesions at first mentioned are external and surgical in character, comprising cutaneous tuberculosis (lupus), suppurative adenitis, and the like. In the majority cure has resulted. The diseases are arrested and much involution follows. Pissavy has reported these findings before one of the medical societies with special reference to some joint cases—knee and ankle—in which the results were striking. On the other hand, in a case of tuberculous osteitis in which there were numerous foci the treatment was wholly ineffectual. In every one of the cases reported by Pissavy general improvement was noted irrespective of local behavior.

The results were so encouraging that pulmonary lesions were next submitted to trial. There were controlled in all 52 cases which were treated by Grenet and Drouin and by Esnault and Brou. In chronic apyretic forms without hemoptysis the tolerance of the organism to the treatment was perfect and the usefulness of the treatment is for the present limited to this selection. In the opposite type the medication would appear to be mischievous and this applies to acute exacerbations in chronic cases. The course taken by the properly reacting case does not differ from that under other successful plans of treatment. The leucocytosis, however, if this is an index of successful treatment, is very high.

The reviewer, Dr. Mirande, in making his own comments, states that the results merit the title of apparent cures in surgical and certain medical manifestations of tuberculosis. The chief interest in the treatment is that it is perhaps the first example of successful chemotherapy of tuberculosis, assuming, of course, that it acts directly on the bacillus. The results are certainly better than those obtained with salts of gold and copper used on the same theory. But no bacteriolytic power has yet been demonstrated.

SPOROTRICHOSIS AND SURGERY.

MOURE discusses this subject in the Surgical Number of *La Médecine* for October, 1920, ii, 1. The sporotrichum, he states, is the most important of the pathogenic fungi, thus putting it above the ray fungus of actinomycosis. The time has gone by when a cold abscess can be straightway set down to the action of the tubercle bacillus. Histologically there is a close resemblance between the two affections, and in artificially inoculated sporotrichosis tuberculosis is closely mimicked. The fungus is not easily recognized in the sporotrichotic pus. It occurs on vegetables, leaves, fruit, etc., and infection may result from local abrasions and punctures, and by ingesting the parasite. Different types of disease are produced in the inoculation and ingestion types. The gumma produced in the connective tissues resembles that of tubercle and syphilis, while the lesion at the external port of entry with its regional gland packet suggests the primary external lesions of those two affections. The fully developed disease suggests with its polymorphous lesions now one and now the other of the two maladies. On the whole the author adds little or nothing to text book accounts of sporotrichosis. The main point of interest in connection with surgical treatment is negative; surgery is contraindicated, as in the case of syphilis. Potassium iodide clears up one disease as it does the other, and may be used for diagnosis. If the disease clears up, then syphilis has to be excluded. This should be easy, in theory, by serodiagnosis, but the author does not even mention the Wassermann, laying the full diagnostic stress on locating and recognizing the sporotrichum.

LION BITES.

Dr. BODI, of the Italian Somaliland, gives an account of lion and leopard bites in the *Giornale di medicina militare* for October 1, 1920, lxviii, 10. Many deaths occur annually—almost entirely among the indigenous—in which either one of the felidæ or the crocodile is accused. There is a notable difference between the wounds inflicted by the felidæ and the reptile in question, for the former, which attack living victims only, inflict clean wounds. The crocodile, on the contrary, secretes its carcasses until they become decomposed. In Benadir—the Italian Somaliland—the lion does not attack mankind by choice, preferring cattle and goats; but nevertheless the beast is greatly feared by the natives, who use reason in dealing with the leopard and crocodile, but are thrown in panic by the larger cat. When the natives *en masse* attack the lion reprisals may occur as in the case narrated by Boidi in which several of the attacking party were injured. One subject received four or five lacerated and contused wounds over the breast. The author irrigated these with physiological serum and then applied iodine tincture. Seventeen suture points were inserted. These measures, however, were not satisfactory, for by the fourth day healing had not begun and there was a distinct gangrenous odor which heralded the formation of a great necrotic defect. It became apparent that gas gangrene was at work, which involved the musculature of the anterior thorax. The cavity which formed suggested

the marsupial pouch of the Australian mammal, and drainage became impossible by the openings already present. The author made counter incisions over the abdomen, and by means of irrigation and iodoform gauze the cavity was eventually made to heal, and sixty days after the lion's attack the condition was satisfactory. The experience was altogether exceptional in lion bites among the aborigines.

News of the Week.

Pre-Nuptial Physical Examinations for Women.

—The Oregon Legislature has passed a bill requiring women as well as men applying for marriage licenses to be examined as to mental and physical fitness. A law requiring examination of men has been in force for some time in Oregon.

More Children Die from Accident Than from Epidemic Disease.—Statistics compiled by the American Red Cross show that accidents take the lives every year of 20,000 children under the age of fourteen years. The figures show that 167 out of every 1,000 child deaths, between the ages of five and nine, are due to accident, while between ten and fourteen years the ratio is 177 to 1,000. In the year 1917, there were more deaths from accident than from epidemic disease, the percentages being 17.7 for accidents and 17.1 for epidemic disease.

Druggists Protest Against Narcotic Rules.—The new regulations issued by the New York State Department of Narcotic Drug Control, with the alleged intent of more effectively coping with the illicit use of drugs, were condemned by the pharmaceutical societies throughout the State at a hearing on February 21. The druggists particularly object to the regulation requiring them to copy prescriptions and dispensing blanks in triplicate, as it will impose an unnecessary burden on them and will not in the smallest degree affect the sale of narcotics to addicts since such sales are confined to illicit purveyors. The regulations became effective on March 10 unless the pharmacists and physicians make a protest sufficiently vigorous to influence Commissioner Herrick to take other action in reference to the ruling.

Measures Against Typhus in Italy.—Signor Corradini, Under-Secretary of the Interior, has issued a statement declaring that the Italian Government is taking vigorous measures to prevent the entrance into Italy of infectious diseases, especially typhus. Dr. W. W. King of the United States Public Health Service, usually stationed at Naples, has been ordered to Trieste where he will cooperate with the Italian authorities in handling the typhus situation.

Health Officers Confer on Typhus Situation.—At a conference of the State Health Officers of all the northern tier of seaboard States and the United States Public Health Service, held in Washington, February 26, plans were made to coordinate the quarantine work of the different North Atlantic ports. Additional facilities will be provided in New York and Baltimore. The Secretary of the Treasury will be asked for an additional \$20,000 for improvements.

Government Pays for New York Quarantine Station.—The Federal Government has sent a check for more than \$1,500,000 to the Treasurer of New York State in payment for the quarantine

station on Hoffman Island. Dr. Leland C. Cofer will be retained as Health Officer of the Port and will be granted additional facilities.

Child Health Demonstration.—The National Child Health Council announces plans for a child health demonstration in some one community in the United States. The object will be to assist the community in working out a well-rounded program for the health of its mothers and children. This will be one of the steps in the development of a comprehensive and well-balanced child health program on a national scale. A test of the soundness and permanency of this demonstration will be the permanency of the results in the life of the community. For that reason the attitude of the citizens and officials toward it will be one determining factor in the selection of the community. Announcement will be made within a few weeks of the plans of the Council as to the selection of the community and of the conditions which are considered desirable in order that the demonstration may be of most service to the country. Organizations represented in the National Child Health Council are the American Child Hygiene Association, American Red Cross, Child Health Organization of America, National Child Labor Committee, National Organization for Public Health Nursing, and National Tuberculosis Association.

Steel Corporation Approves of Rehabilitation Hospital.—Officers of the Reconstruction Hospital for the Rehabilitation of Industrial Casualties announce that the Carnegie Steel Corporation is the first large industrial corporation to pledge support to the hospital. Dr. William O'Neill Sherman, chief surgeon of the corporation, in a telegram to the hospital authorities said it would be easy to prove the humanitarian and economic value of the hospital and that it was only a question of time until such institutions would be functioning in every large city and industrial center in the country.

Maternity and Baby Bill Held Up.—Final passage of the Senate maternity and baby welfare bill at this session of Congress has been made doubtful by the refusal of the House Rules Committee to give it privileged status.

Investigation of Fox Hills Hospital Asked.—The Executive Committee of the American Legion, Department of New York, announces that it will recommend a Congressional investigation of conditions at the Fox Hills Hospital, Staten Island. Certain of the committee have visited the hospital and state that the buildings are wholly unsuited for sick and wounded; that there is lack of discipline and control of patients; there is a lack of doctors and nurses, and that very unsanitary conditions were observed.

Smallpox in New York.—Recently three cases of smallpox were reported to the Department of Health within four days. In all nine cases of smallpox have been reported since January 1, as compared with 25 for the same period of last year. In one of the three recent cases the victim had entertained twenty-one friends within three days from the time his disease was diagnosed. These inspectors of the Health Department are endeavoring to locate.

"Siamese Twins" Arrive.—A showman has just arrived in this country with "Siamese twins," which

he has brought from Czechoslovakia. The twins are forty-three years of age and one is the mother of a healthy and normal son ten years of age. The twins were shown privately to physicians in New York and then taken away to begin a show tour.

Typhus Case Develops on Twentieth Day.—Dr Leland C. Cofer, Health Officer of the Port of New York, announced on February 26 that another case of typhus fever had been discovered among the immigrants detained on the Italian ship *San Giusto*, which arrived three weeks ago with twenty cases of typhus among her passengers. This makes the thirty-fourth case at Quarantine. The fact that twenty days elapsed in this case before symptoms of the disease manifested themselves has decided the New York Health Department to continue its inspection of typhus suspects for twenty days.

Health Work in Industry.—The National Industrial Conference Board in a recent report states that health service in industry and the economic value of medical inspection of workers has proved so satisfactory that it has become an integral part of industrial organization. In a recent investigation by the Conference Board of Physicians in Industry it was found that thirty-four plants, representing fifteen industries, employing 400,000 men, have introduced physical examination of workers, all to immense advantage.

Harvey Society Lecture.—Dr. S. B. Wolbach, Associate Professor of Pathology and Bacteriology, Harvard University, will deliver the Eighth Harvard Society Lecture at the New York Academy of Medicine, Saturday evening, March 12. His subject will be "Typhus Fever and Rickettsia."

New York Infirmary for Women and Children Again Open.—This institution which has been remodelled and newly equipped was formally opened at a reception given by the Trustees and Medical Board on the afternoon of February 24. Dr. Simon Flexner spoke on "Lethargic Encephalitis and Allied Pathological States."

Scholarships in the New York Post-Graduate Medical School and Hospital.—Under the terms of the Oliver-Ren Endowment there will be available this year six scholarships providing in full the expenses of tuition at the New York Post-Graduate Medical School. The scholarships are open to practising physicians of the United States, but according to the wishes of the donor, physicians of Pennsylvania will receive preference. Applications may be sent to the President of the New York Post-Graduate Medical School and Hospital, Twentieth Street and Second Avenue, New York City.

The Late Dr. Eva H. Knight.—The following minute was adopted at a meeting of the Women's Medical Association of New York City on February 16, 1921: The Women's Medical Association of New York City has learned with sincere sorrow of the death of Dr. Eva Helen Knight. In the death of Dr. Knight, this Association and the medical profession have lost a colleague who enjoyed the respect and affection of all who were privileged to know her. Through her long years of public medical service, first as physician to the Board of Health and later as physician to the Board of Education, she was a real force in promoting the health of the teachers and children of the city of New York. Dr. Knight's work in this field was untiring and she brought to it in addition to her thorough profes-

sional training, a sprightliness of personality, and loyal comradeship that made her trusted and loved by her medical associates, her patients and the teachers and pupils of the city.

In Dr. Knight's death, this Association and the medical profession have suffered a great loss, and it is but fitting that we record the affection and esteem which we felt for her, by spreading this resolution on our Minutes and sending a copy to her family and to the medical journals.

EMILY LEWI, *Chairman*,
ANGENETTE PARRY,
FRANCES COHEN.

Obituary Notes.—Dr. J. Russell Taber of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, N. Y., in 1874, died suddenly of heart failure, on February 22, at the age of seventy years.

Dr. EDWARD MOSES CHILDS, a graduate of the New York Medical College in 1877, died suddenly of heart disease at his home in Brooklyn, on February 23, at the age of sixty-nine years.

Dr. KATE J. JACKSON of Dansville, N. Y., a graduate of the Women's Medical College of the New York Infirmary in 1877, died at the home of a relative in South Livonia, N. Y., on February 24.

Dr. WILLIAM J. JONES, JR., a graduate of Cornell Medical College in 1899, died at his home in New York City on February 25.

Dr. TOBIAS GERHART of Angelica, Pa., a graduate of the Medical Department of the University of Pennsylvania, in 1864, died on February 21, at the age of eighty-five years.

Correspondence.

CENTENARIANS AND OVER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In your issue of February 26 appears a paragraph headed "Woman Reaches Ripe Age of 109." This type of unauthenticated statement may pass in the lay press, but should not go without question in a scientific journal.

I have collected the biographies of more than 100 persons who lived to be a little more than centenarians and I have yet to find an authenticated case of the duration of life beyond 103 or 104 years. The cases of those living beyond this age, where attempts have been made to prove them, are found almost always to refer to Indians, Negroes, or some ignorant foreign peasant; persons who have no accurate family records and who lived at a time and place where no accurate vital statistics were kept.

I recently read in a lay paper, of a woman in a Yiddish Home, alleged to be 110 years of age. I went to see her and she turned out to be an ignorant Russian peasant, who might have been a few years over 90. I unwittingly nearly caused her death, for I sent in a photographer to take her portrait; when he touched off a flash light, she thought the devil had come for her and went into hysterics followed by serious collapse!

Centenarians find their age a subject of interest and curiosity, and this, combined with poor memory and the fact that all who knew them in childhood are usually dead, often leads to gross exaggeration regarding their age.

I should be exceedingly interested if we could obtain a careful physical examination and physiological study of a genuine case of a person living beyond 103 or 104 years of age.

NEW YORK.

W. GILMAN THOMPSON, M. D.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, February 8, 1921.

Medical Developments at University College, London.—The Rockefeller gift of £1,250,000 to University College, London, has rendered possible many important medical developments which are now beginning to be inaugurated. The Senate of London University is about to establish a Chair of Embryology in the Faculty of Medical Sciences at University College, and the first occupant of the Chair will soon be appointed. The appointment will be a whole time one and the salary will be £1,000. Moreover, a site has now been decided upon for the new Anatomy Building provided for by the Rockefeller gift. It is to be built in Gower Street adjacent to University College and University College Hospital. The houses which at present occupy the site are being demolished. It is expected that building operations will begin in October, 1922. It is interesting to note that it was in one of these houses that Darwin commenced to write his "Origin of Species."

There is also to be instituted at University College a Readership in the History of Medicine, to which Dr. Charles Singer has been appointed.

A Gynecological Clinic at the Royal Free Hospital.—A new departure has been made in the medical education of women by the appointment of a woman professor to fill the recently established Chair of the Gynecological and Obstetrical Clinical Unit established at the London Royal Free Hospital School of Medicine for Women. This unit is part of the scheme just instituted in London University, whereby professors paid by the University and abstaining from private practice, are in future to take the place of practising surgeons and physicians, unpaid by the University, in the training of students in the hospital wards. The original scheme was to set up twelve units, and up to the present time two units have been organized at St. Bartholomew's Hospital, two at University College Hospital, two at the London Hospital, one at St. Thomas's Hospital, and now one at the Royal Free Hospital. That at the latter institution is the first to be established in gynecology, a subject which it certainly seems ought to be the special province of medical women. In addition, prenatal clinics are to be developed at the Royal Free Hospital on a really adequate scale, on a scale indeed which as yet has not been attempted. The new unit is to consist of sixty-eight beds, twenty-three gynecological and forty-five obstetrical.

Congress of Radiology and Physiotherapy.—A great deal of interest is being taken at the present time in radiology and especially in physiotherapy, which is now taught on scientific lines in most of the medical schools. Therefore American medical men will like to know that a congress organized by the Electrotherapeutic Section of the Royal Society of Medicine and the British

Association of Radiology and Physiotherapy will be held this year in London on April 14, 15, and 16. Sir Humphry Rolleston will be the president, and there is a long list of vice-presidents. Dr. G. Harrison Orton is the secretary general, Dr. Stanley Melville and Dr. I. Justin Wilson are the Hon. Secretaries for General Correspondence; Dr. N. S. Finzi is the Hon. Secretary for Radiology; Dr. G. Murray Levick for Electrolgy, and Dr. C. V. Mackay for Physiotherapy. The provisional program contains the titles of many papers to be read by French, Belgium, and British delegates.

Report on Influenza.—A really remarkable report on influenza has been sent out recently by the Ministry of Health. It is too long to detail and too technical in parts to refer to or to quote from at length, it must suffice to deal briefly with a few of the facts adduced and suggestions brought forward. With respect to the influence of weather upon epidemics in general and upon influenza in particular, the investigators who give their results in the report say that these results are sufficient to establish a *prima facie* case in favor of the view that an unseasonable deviation of weather on the side of coldness played some part in the mortality of the epidemics. They not less clearly testify against any claim that weather conditions rank among the primary factors of the pandemic or epidemic prevalences. They state that there may be complete confidence that the cruder generalizations of the old hypotheses are unsound, and that the part played by the meteorological peculiarities of the pandemic years was a minor one. The report is the most exhaustive ever published on the subject. Dr. Herbert French gives a full description of the clinical features of the disease, and especially of the pneumonic type, if it may be so termed, as observed by him and colleagues in military camps. Professor Andrewes discusses the bacteriology, but arrives at no definite conclusions. He is inclined to think that the Pfeiffer bacillus, so long believed to be the primary cause and still so believed by some, is a secondary infection. As for a filter-passing virus being the primary cause, Andrewes is non-committal, as while he deems this view suggestive, he says what is obviously true that the evidence in favor of this hypothesis is not sufficiently convincing for a final verdict to be given. He also says what is equally evident that the complications to which the pandemic has owed its abnormal mortality have been due to secondary infections, but whether when he goes on to say, in which Pfeiffer's bacillus and the hemolytic streptococcus have played the predominant part he is on quite such sound ground may be open to doubt. Certainly all evidence goes to show that the hemolytic streptococcus has played a sinister rôle as a complication, but it appears to be somewhat begging the question to place Pfeiffer's bacillus among the secondary infections until more confirmatory proof has been given that such is the case than has been forthcoming as yet. A large number of observers are still of the opinion that Pfeiffer's bacillus is the primary cause. It may be said that the report deals with every phase of the influenza problem and is one that reflects the greatest credit on the contributors and compilers.

6. Benign Growths of the Stomach. A. S. Merrill.

1. Hemorrhage from the Stomach and Esophagus.—Lund and Foley report four illustrative cases. In acute cases the ulcer may heal while the stomach is kept at rest in the treatment of the first hemorrhage, so that the bleeding is never repeated. In chronic ulcer there has been a generally accepted dictum that after a second hemorrhage one should operate. This may be a good working rule, but it is also a fact that the second hemorrhage may be fatal. The use of the actual cautery in operations for ulcer has greatly simplified the treatment of hemorrhage and made it much safer than before, while transfusion furnishes a ready means of changing a patient at once from a bad to a good operative risk. It is safer to transfuse and operate at once and cauterize the ulcer than to wait the doubtful result of a second profuse hemorrhage. In order to cauterize the ulcer, however, one must first find it; and it is well known that superficial ulcers can sometimes not be seen or felt through the stomach wall from the outside. They can be found by passing the wall of the stomach in review, so to speak, through an opening in the anterior surface. The presence of the "sentinel gland" is an aid in the finding of the ulcer. A positive x-ray may also aid in the location of the ulcer.

8. The Medical Student's Problem. George H. Hyslop.

5. Exophthalmic Goiter and Surgery.—Israel Bram, in the concluding paper on this subject, summarizes as follows: Surgery is indicated in Graves' disease when: 1. Marked pressure symptoms of cervical and thoracic structures are evident. 2. Malignant degeneration of the thyroid occurs. (Marked pressure symptoms and malignancy are unusual occurrences during the course of thyroid hyperplasia.) 3. A local structure (tonsils, appendix, pelvic abnormalities), which, by a careful process of exclusion, is found to have an etiological bearing on the syndrome. Surgical removal of such diseased tissues, in breaking the continuity of the vicious circles upon which the symptom complex depends, may bring about a cure. Surgery is indicated in the vast majority of cases of Graves' disease, for: 1. The pathogenesis of the disease points to the thyroid as playing but a small part in the causation of the syndrome. 2. The symptomatology of the affection is as widespread as the body itself, favoring strongly the pluriglandular theory. 3. Physiology indicates that, in the human being, it is almost as dangerous to attack surgically an overactive organ, such as the thyroid, as to attack surgically an overactive heart. 4. On clinical grounds Graves' disease does not fall in the realm of surgery, as indicated by the considerable mortality rate, frequent operative accidents (e.g. myxedema, tetany, vocal paralysis), postoperative sequelae (acute exacerbations, acute psychoses), recurrences, and the lack of conclusive proof of complete surgical cures. As has been suggested, surgical interference with the thyroid, by reducing the recuperative powers of the patient, prolongs the state of invalidism and favors profound de-

generative changes of the tissues of the circulatory and nervous systems, rendering the prognosis less favorable and the task of the internist tedious. 5. On empirical grounds, Graves' disease belongs strictly in the field of the internist, who, having made endocrinology his field of special endeavor, is capable of demonstrating complete and permanent non-surgical cure of every case of the disease in which the vital structures are not badly damaged and a reasonable degree of cooperation is obtainable.

7. Some Toxicological Aspects of Surgical Rubber Goods.—Walter I. Galland gives the following method for the rapid qualitative determination of the presence of antimony or lead in a rubber article: Cut up about a gram of the rubber into fairly small pieces with scissors, and place in a porcelain casserole or evaporating dish. Add five to ten c.c. of concentrated nitric acid, and heat gently on an asbestos board over a Bunsen flame. It is best to carry out this reaction under a hood. Evaporate to approximate dryness, and add five to ten c.c. of concentrated hydrochloric acid. Boil gently until chlorine fumes cease to be evolved, adding sufficient hydrochloric acid to make up for loss by evaporation. Do not continue boiling too long a time, as antimony chloride is definitely volatile. Add one hundred c.c. of water, stir and filter, and pass hydrogen sulphide through the heated filtrate till thoroughly saturated. A yellow precipitate is presumably antimony (or arsenic). The antimony precipitate will dissolve in warm yellow ammonium sulphide solution. A black precipitate is most probably lead. The lead precipitate is insoluble in the ammonium sulphide solution. Summarizing, the writer emphasizes the following points: 1. Manufactured rubber contains many substances added in the course of manufacture, some of which may be poisonous. 2. Antimony pentasulphide is present in many rubber compounds, and can be dissolved from the rubber by various solvents. 3. It is possible that antimony may at times be dissolved from tubing by alkaline arsenaphenamine solutions. 4. The presence of poisonous substances in rubber compounds destined for medical or surgical use is a menace. 5. Rubber compounds can and should be manufactured for surgical use free from deleterious substances.

2. A Comparison of Rectal with Colon Injections of Eupinephrin, with Reference to Pressor Effects and to Glycosuria.—Barbour and Rapoport, in this determination, conducted two series of experiments on rabbits, the first series dealing with the effects of the respective injections on blood pressure, the second on the carbohydrate metabolism. The results on blood pressure are summarized as follows: 1. An injection of 1 mg. of eupinephrin per kilogram caused greater increases in the blood pressure of rabbits when given by rectum than when injected into the colon. The average blood pressure increase after rectal injections was 11.5 mm. of mercury; after colon injections, 4.2 mm. of mercury.

2. The highest rise of blood pressure observed in all of the experiments, due to an injection of 1 mg. of epinephrin per kilogram into the rectum, was 28 mm., while the highest rise from a similar amount into the colon was 12 mm. 3. The earliest effect on the blood pressure after the epinephrin was injected into the rectum was seen in thirty seconds, whereas the earliest effect after an injection into the colon was seen in 150 seconds. 4. The average time necessary for a maximum effect on the pressure after the rectal injections was 141 seconds; after the colonic injections, 275.8 seconds. The effects on carbohydrate metabolism are summarized as follows: 1. Colon injections of epinephrin in rabbits gave more profound glycosuria and diuresis than rectal injections. 2. The average amount of dextrose obtained from injecting 0.5 mg. per kilogram into the colon was 0.158 gm., while from the rectal injection it was 0.088 gm. 3. The greatest amount of dextrose obtained from the injection of 0.5 mg. of epinephrin into the colon was 0.208 gm., while the greatest amount obtained from a rectal injection was 0.121 gm. 4. The average twenty-four hour urine volume after injecting 0.5 mg. epinephrin per kilogram into the colon was 142.5 c.c.; after injection into the rectum it was 120 c.c. From these experiments it is concluded: 1. Epinephrin is absorbed both from the rectum and from the colon in rabbits. 2. Injected into the rectum, epinephrin causes a greater rise in blood pressure than when injected into the colon. 3. When epinephrin is injected into the colon it causes a greater degree of glycosuria and diuresis than when injected into the rectum.

8. The Prognosis of Nephritis in Childhood.—Richard F. James undertook the study reported to determine (1) how many patients that had had acute nephritis recovered entirely; (2) how many developed the chronic type; (3) the present condition of the chronic type; (4) the ultimate prognosis. During the last sixteen years he has examined in the Children's Hospital seventy children who had had nephritis. The examination included the cardiovascular system, hemoglobin, uranalysis, present health of the child, record of the patient's condition while under treatment, and the etiology. It seemed that nephritis has its etiology chiefly in such acute diseases as may be caused by infections with organisms of the streptococcus, staphylococcus or pneumococcus type. Sixty-seven patients were admitted originally with a diagnosis of acute nephritis and three with chronic nephritis. Nine of the sixty-seven cases, or 13.3 per cent., terminated in the chronic type, and of these only two could be considered severe. The average age on admission was 6½ years, the oldest patient being 12, the youngest 2. At the time of the examination the average age was 10; the oldest patient was 19, the youngest 4. The average length of time observed after discharge from the hospital was five years; the maximum, sixteen years; the minimum, three months. All of the sixty-seven patients who had had acute nephritis are living under normal conditions, on ordinary diet; and in every case the urine was found to be negative. This fact is considered of importance in that it signifies that kidneys that have been injured are no more susceptible to infection than normal kidneys. The histories of five cases are recorded to show the possible time that elapsed during which there was no recurrence despite the fact that several of the patients had acute infections during that period. In the group of twelve chronic cases the etiology was as follows: tonsillitis, four; following appendectomy, one; measles, one; purpura, two; scarlet fever, four. The two most severe cases followed purpura. The average age on admission was 7 9/12 years; the oldest patient was 11 7/12 years, the youngest 2 years. The average age at the time of examination was 11 years, the oldest patient was 14½, the youngest 6 5/12 years. The average length of time seen after discharge was two and one-twelfth years, four were seen five years and two between one and two years after discharge. Of the twelve patients examined eight had albuminuria, four did not. The writer considers that in acute nephritis the greater percentage of patients recover absolutely, yet no one is justified in saying a child is well by one or several negative urinary findings, until after the child has lived under ordinary environment and on a regular diet for a considerable period. Then, with the urine negative, chemically and

microscopically, one may say the child is cured. The prognosis in the acute exudative type, with edema and a diminished urinary output, is less favorable than in the acute hemorrhagic type without edema. In the chronic type there is no specific guide to prognosis. Patients with mild chronic nephritis recover. Diseased portions may recover even if there is considerable degeneration, and neighboring portions of the kidney may hypertrophy and carry on the extra work. It is surprising to see the amount of damage a kidney may receive and yet apparently recover. Many will stand severe infection without acute exacerbations of nephritis, but they are more prone to follow upper respiratory infections.

2. Legg's or Perthes' Disease. The Differential Diagnosis of Affections at the Hip in Children.—H. Buckley Roderick places affections at the hip in two groups: (1) those in which there is pain and muscular rigidity, restricting movement of the joint in every direction, the most common and important member of this group being tuberculous disease of the hip; (2) those in which there is little or no pain and no muscular rigidity, but rather undue mobility or restricted movements in certain directions only. Under this group fall congenital dislocation of the hip, coxa vara, coxa adducta, and Legg's or Perthes' disease. After careful and methodical physical examination has been made and an opinion formed as to the nature of the case the patient should be referred to the radiologist for skiagraphic evidence, not, as is so often done, for diagnosis. X-ray diagnosis unsupported by clinical evidence is sure, sooner or later, to lead to serious error. The surgeon and the radiologist should work together. This is but another example of the value of "team-work." It is essential that both joints should be photographed. In order to minimize errors of reading which may result from differences in exposure, developing, or the position of the plates in relation to the bones, both hips should be taken on the same plate. The sound joint is the only reliable control. In cases of early hip disease the changes may be so slight that without the sound side to compare with it is almost impossible to be certain as to the normal outline of the bone, or as to whether there is narrowing of the shaft due to atrophy, abnormal transparency of the bone (osteoporosis), or whether the gap, representing the articular cartilages on the head of the femur and acetabulum, is of normal thickness, or whether small foci of disease exist. The writer reiterates the necessity of the surgeon and the radiologist working together. The clinical picture and the skiagram are often diametrically opposed. In tubercle, for instance, physical examination, on the one hand, finds a subject with pain and fixed hip joint with consequent grave disability. The X-ray, on the other hand, especially in cases of primary synovial infection, may show nothing at all, whereas in Legg's disease the radiologist may be staggered by the alarming picture presented by the skiagram, while the surgeon finds a patient with little or no disability. Team work is the keynote of future medicine and surgery. It is thus and thus only, that the best results will be obtained.

4. Action of Quinine on the Pregnant Uterus.—Hugh W. Acton summarizes the experiments conducted to determine the ecbolic action of quinine as follows: The action of quinine in certain concentrations causes con-

traction of both the longitudinal and circular fibers of the uterus. The effect produced depends on the concentration of quinine present—weak concentrations, 1–300,000, have no effect; concentration of 1–150,000 produce contractions under certain conditions, while a concentration of 1–44,000 produces a tonic spasm, which, if sustained, would cause asphyxia of the fetus from constriction of the placental sinuses. This concentration could only be attained if the patient was nearly poisoned by a large dose of quinine. The degree of concentration in the blood varies with the dose taken and on individual susceptibility depending on the rate of absorption. Cinchonism is correlated with the concentration of quinine present in the blood and varies with different individuals, and is more frequently seen with weak and anemic persons. Concentrations of 1–150,000, such as occur with large doses, increase the strength of the intermittent uterine contractions, and if some exciting cause was present—e.g., weak membranes or a patulous or dilated os—the pressure produced by the increased contractions might be sufficient to cause rupture of the membranes or dilatation of the os, and so bring on labor. The therapeutic recommendations which the writer makes are: 1. The controlling of the fever by quinine or other cinchona alkaloids must be the first objective in the treatment of these cases. We know that high temperatures soon cause death of the fetus, and this factor is sufficient to induce premature labor. The mother's temperature should be carefully watched and prevented from exceeding 103 degrees F. by sponging, etc. 2. The avoidance of large doses of these alkaloids. As soon as the diagnosis of malaria is made, which is an urgent matter in pregnancy, quinine or quinidine should be given at once as the case requires. It is better to divide the doses into 2½ or 5 gr. doses given every two or four hours; 20 gr. a day is sufficient, and ample to control any attack of malarial fever. 3. The employment of general methods for the prevention of miscarriage, viz., complete rest in bed and the judicious use of opium in allaying any mental excitement. When the child is dead or the miscarriage inevitable, quinine should be given in ordinary doses and the case treated on general obstetrical lines.

4. Rotation-Dilatation of the Astragalus. Robert Ollershaw.
5. On the Probable Identity of *Rickettsia pediculi* with *Rickettsia quintana*. A. Bacot.

1. The Theory of Disturbed Reflexes in the Production of Symptoms of Disease.—Sir James Mackenzie enunciates and develops the theory that the vast majority of the symptoms of disease are disturbances of normal reflexes. In many diseases all the symptoms on which a diagnosis is based are reflex in origin—in some the reflexes are disturbed by the entrance of the stimulus through the nervous system, and in others the disturbance is through the circulation. To the former belong the symptoms of such diseases as gastric ulcer, renal calculus, gall-stone disease. The symptoms in infections are due to the disturbance of the reflexes through the circulation, as influenza, malaria, typhoid and typhus fevers, measles, and abscess formation, apart from the swelling. In some diseases one gets a mixture of both kinds of reflexes, as in appendicitis, where there is not only the local pain and tenderness of the tissues of the external body wall, with contraction of the muscles of the abdomen, but the feeling of exhaustion, rapid pulse, tendency to vomit. In cholecystitis one gets a similar complex. The need for the more accurate recognition of symptoms is seen when it is considered how difficult it is to diagnose even such seemingly simple affections as gastric ulcer and appendicitis. Though surgeons have been operating for these complaints for many years, the most experienced recognize that in many cases they find they have been mistaken in their diagnosis. This is due in a great measure to the fact that the nature and mechanism of

the symptoms of these diseases have never been understood, and the symptoms were never clearly differentiated from those of other diseases which they resemble. It will thus be seen that symptomatology is like chemistry, where the combination of elements results in the production of a great number of compounds bewildering in their variety. Nevertheless, as in chemistry, when they are subjected to strict analysis they can be resolved into their component elements. When the analysis of symptoms is studied as fully as the analysis of chemical compounds has been studied, then it will be possible to group the disturbed reflexes in an orderly manner. The next step then will be to find out the agents capable of provoking the different reflexes, so that we get nearer to the immediate cause of disease. The employment of this method of investigation is but a return to those methods of clinical research which were so fruitful in their results in the past, especially during the early half of the nineteenth century. To realize how great the progress was during that period one must consider the discoveries associated with the names of Addison, Bright, Graves, Adams, Stokes, Cheyne, Paget, Hodgkin, and Jenner. These observers employed the most useful of all weapons in research—the trained senses. A certain number of symptoms are due to structural changes and functional derangements. These are generally shown by physical signs, and are due to departures from the normal in various ways, as in alteration in the size and shape and consistency of organs, changes in the color, as pallor, modifications of the sounds of the heart and lungs. The writer does not discuss these in the present contribution, but holds that they must be reconsidered in view of the theory which he propounds of disturbed reflexes, because many apparently structural and functional signs are really disturbed reflexes, or are produced by disturbed reflexes.

2. A Preliminary Note on the Histopathology of Epidemic (Lethargic) Encephalitis.—C. Da Fano states that in the nervous tissue from cases of epidemic (lethargic) encephalitis within and without the nerve cells minute forms have been observed, to all appearance consisting of a central generally basophil particle and of a delicate little stainable body, irregularly round or oval in shape. For these forms the term "minute bodies" is *pro tempore* proposed. The bodies are generally discrete, and provided with one granule, but dumbbell-shaped forms occur as well as others with two central particles arranged in pairs. As an yet not quite definable relation seems to exist between these forms and a granular, pigment-like material occurring within the nerve cells in places where brown or black pigment is not generally found. Minute forms, similar in shape, structure, and staining properties to those observed in the nervous tissue, have been traced within and without the cells infiltrating a salivary gland from an acute case of the disease. After discussing the supposition that such findings might be the product of an optical illusion, associated perhaps with degenerative changes caused by the malady, the suggestion is tentatively put forward that they may be due to the presence in the tissues of a living agent, cause of the disease.

2. **The Bacteriology of Infected Wounds with Especial Reference to the Importance of Streptococcus Haemolyticus.**—Theodore H. Sweetser based this communication on an analysis of bacteriologic work done at Base Hospital 15, American Expeditionary Forces in France. Interesting results were obtained from the consideration of the following points: 1. The character of the bacterial flora found in wounds after the lapse of various periods of time. 2. The symbiosis of organisms in wounds. 3. The prognosis of cases showing the presence of certain organisms. 4. Secondary suture of wounds. 5. Gas infection. 6. The bacterial infection to be most feared in cases of gunshot wound, i. e., streptococcal bacteriemia. His observations are summarized as follows: 1. Anaerobes are prominent in the early bacteriologic picture of wounds but disappear in a short time. Aerobes become progressively more prominent. The streptococcus has a fairly constant incidence and is very persistent. 2. A combination of streptococcus hemolyticus and staphylococcus aureus was the most common of all associations in wounds. That association was particularly frequent in fatal wounds. Streptococcus hemolyticus, staphylococcus aureus, bacillus Welchii, bacillus coli communis, bacillus proteus, and to a less extent, staphylococcus albus, were the bacteria appearing most often in both the fatal and non-fatal cases. 3a. (1) The prognosis seems to have been good in cases showing staphylococcus aureus or other aerobes aside from streptococcus. Here the most interesting point is that an association with staphylococcus aureus seemed to lower the virulence of infection with anaerobes. (2) Infection with anaerobes showed a high death rate, but a short period of danger to life, unless the anaerobes were associated with streptococcus. (3) Deaths from streptococcus infection were numerous and occurred at least up to the end of the fourth month. The mortality was even higher where streptococcus was associated with staphylococcus aureus or with anaerobes. 3b. Conversely: Cases fatal early usually showed anaerobic infection; those dying late invariably showed streptococcus infection. Most of the early improvements and cures were cases of infection by aerobes other than streptococcus, while the improvements and cures that were tardiest generally showed infection by streptococcus without anaerobes, or by streptococcus and staphylococcus aureus without anaerobes. 4. Secondary suture of wounds failed in some cases apparently because the interval between the injury and primary surgical treatment had been too long, and in other cases because the secondary suture was attempted too soon. 5. Gas infection was most often found in wounds of heavily muscled parts of the body; fracture of bone was not an essential factor; anaerobes frequently contaminated without infecting wounds. 6. A streptococcus bacteriemia was apparently by far the most important cause of death in cases of gunshot wound. 7. The culture of infected wounds is certainly valuable, even if only for the purpose of determining the presence of streptococcus hemolyticus.

8. **The Production by Chemical Means of a Specific Cholecystitis.**—F. C. Mann carried out this investigation, not because of the possibility of its having any direct bearing on the condition as it occurs in man, but because it offered an opportunity to observe the production by a chemical of an inflammation of a particular organ. It was found that the intravenous injection of a solution of chlorinated soda in dogs produces a definite reaction of the gall-bladder in a high percentage of experiments. The reaction consists of a breaking down of the capillaries and infiltration of the wall of the gall-bladder with blood. To produce the reaction in the gall-bladder it is necessary to inject relatively large amounts of the solution, at least more than 5 c.c. for each kilogram. The reaction takes place very shortly after the injection, and is completed within the first twelve to twenty-four hours. The reaction is undoubtedly produced by some chemical in the solution; chlorin is suggested as the possible substance. All solutions, however, even though their chlorin content may be practically the same, do not give the same

percentage of gall-bladder reactions; it would thus appear that a factor other than the chlorin content was involved. The solution reaches the gall-bladder through the blood stream, and a gall-bladder in which the blood supply, particularly that coming from the liver, is generous, develops the most marked reaction. In some instances a definite chronic condition has followed the acute condition.

3. **The Mechanism of the Carrier State, with Special Reference to Carriers of Friedländer's Bacillus.**—Arthur L. Bloomfield found it possible to show, in the case of Friedländer bacillus carriers, that the breeding place of the bacteria is in a definite focus—the tonsil. From this point the organisms are discharged into the open pharyngeal cavity, and at times may be introduced into the nose. There is no evidence, however, to indicate that any adaptation takes place between the bacilli and the mucous surfaces, leading to actual growth and multiplication on these surfaces. They react as the normal mucous membranes do, both upon the introduction of the carrier's own strain, or the introduction of a second strain of Friedländer's bacillus. Of the eighty-five unselected individuals studied in this investigation, 5.8 per cent. were found to be carriers of Friedländer's bacillus. The carrier state persisted throughout the observation. There was no tendency for contacts to acquire the carrier state. Differential cultures showed the breeding place of the Friedländer bacilli to be in the tonsil. The carrier's own strain or a foreign strain of Friedländer bacillus implanted upon the free surfaces of the mucous membranes disappeared at the same rate of speed as in a non-carrier. It was impossible, artificially, to produce a carrier state by repeated inoculation with *B. Friedländer*. The general conclusion from these observations is that the carrier state depends on a focus of diseased tissue which affords a breeding place for the bacteria. They do not become adapted to growth on the free surfaces of the mucous membranes.

4. **Tuberculosis of the Kidney in Women.**—Leo Brady formulates the following conclusions from his experience with seventy-seven cases of tuberculosis of the kidney in women: 1. In our cases of renal tuberculosis, in 18 per cent. there has been a family history of tuberculosis. 2. In 60 per cent. of the cases of tuberculosis of the urinary tract the lesion has been in the right kidney, in 35 per cent. in the left kidney, and has been bilateral in four patients. 3. Renal tuberculosis occurs most frequently between the ages of twenty and forty, 71 per cent. 4. The average duration of symptoms in our women before coming to the hospital was thirty-three months. 5. Renal tuberculosis in colored women, although not as frequent as in white, is by no means rare. 6. In 88 per cent. of our cases dysuria and polyuria were the first symptoms. 7. One-third of the women complained of hematuria on admission, and in eight patients "smoky urine" was the first symptom. 8. Thickening and tenderness of the portion of the ureter palpable on vaginal examination was present in 32 per cent. of the patients, and this sign is of great help in the early detection of cases of renal tuberculosis. 9. Of the seven patients not operated on, four are known to be dead and the other three left the hospital in a very bad condition and are probably now dead, although we have no definite information about them. 10. The three women on whom simple nephrotomies were performed all did badly. 11. The ultimate result is known in forty-two out of sixty-seven cases in which the kidney was removed, or in 62 per cent. of the cases. 12. Seven of these forty-two patients may

be classed as greatly improved and are now alive, six years after their operations; twenty-five are entirely well with an average period of eleven years since they were discharged from the hospital. This means that 16.5 per cent. of the women of whom we have records have been greatly improved by their operations and 59.5 per cent. have been entirely cured. 13. Comparison of the results obtained when the ureter is removed with the kidney and when it is left *in situ* shows that, although the ultimate results are the same following the two methods, the post-operative sinus heals more rapidly when a nephro-ureterectomy is done, and this, therefore, seems to be the operation of choice when the patient's condition warrants a prolongation of the anesthetic.

4. An Inquiry Regarding the Age and Sex Incidence of Pernicious Anemia. John Eason.

4. An Inquiry Regarding the Age and Sex Incidence of Pernicious Anemia.—John Eason, after calling attention to the current opinion of practitioners and the present-day teaching to the effect that cases of pernicious anemia are most numerous about the middle period of life, submits that there are three chief defects in all published statistics on the age incidence of this disease—two of these so flagrant that they are responsible for an entirely erroneous impression (a) regarding the age incidence and (b) probably regarding the essential nature of pernicious anemia. He presents six charts in substantiation of his views, which he summarizes as follows: (1) Authorities have almost without exception stated that individuals about the middle period of life are specially prone to develop pernicious anemia. (2) Hypothesis and investigations based on hypothesis may proceed on futile lines if this view of the incidence is wrongly maintained. (3) The evidence from a large general hospital of a medical school probably in all cases misleads unless cases of local sick from pernicious anemia alone are the basis of conclusions. (4) On this basis Edinburgh hospitals show the largest numbers between the ages of forty-five and fifty-nine. (5) The rate in these hospitals per 100,000 of the population is highest between fifty-five and sixty-nine. (6) The pernicious anemia death rate figures for Scotland correspond very closely with the Edinburgh Hospital case figures. (7) Until the age of fifty the rate of incidence inclines to be higher in the female than in the male. Thereafter the rate is definitely higher in males than in females. (8) It appears that senility is a more important etiological factor than has hitherto been generally recognized. (9) There appears to be an increasing liability to pernicious anemia with advancing years.

4. Diphtheria and Toxin Antitoxin. Walter D. Ludlum.

4. Diphtheria and Toxin Antitoxin.—Walter D. Ludlum sums up his discussion of this subject as follows: The Shick reaction gives positive evidence of susceptibility or immunity to diphtheria. The use of toxin antitoxin gives immunity to 95 per cent. of those who need it, on whom it is used. Diphtheria kills about 1200 in New York each year. This mortality could be prevented if the entire child population should be protected by toxin antitoxin inoculation, either after demonstrating the need by the Shick test and the limiting of the injections to the susceptible, or by inoculating the whole of them without such test; the degree of protection is equal. The use of this measure should be encouraged to the extent of one's ability.

Gazette des Hôpitaux.

December 11, 1920, xciii, 104.

Industrial Accidents and Dermatoses.—Thibierge cites cases of eruptions which develop in certain workers, as when constant exposure to oil causes outbreaks of pustules. Apparently a mixture of oil and metal dust clogs the pores with resulting acne-like eruption. This was often seen in the war in shell turners, who were forced to use an inferior grade of lubricant. It was clearly from its extreme frequency a professional dermatosis due to the occupation. But eventually it was found to be due to contributory neglect, for as soon as the workers observed the custom of cleanliness the eruptions did not appear. Even the claim that poor oil was responsible could not offset this fact. Among nickel platers it is the custom to plunge the metal to be nicked into an acid bath, using for the purpose pincers with a wooden bite. These baths give off corrosive fumes which tend to cause eczema and the act of immersion further causes a certain degree of splashing so that minute burns result. To this extent the injuries appear to be true and unavoidable accidents of labor. However, when the workman is careless enough to let a piece of metal drop prematurely into the bath or when his pincers slip into the bath and he reaches in after them there is carelessness and contributory neglect, yet according to the courts the said worker may be indemnified. Very nice distinctions have to be made in individual cases to determine responsibility. The vital points to decide are, first, the evolution of the affection which must be in accord with the operation of the alleged cause; second, the possibility of sequelae of the original injury, and, third, the possibility of simulation.

La Presse Médicale.

December 18, 1921, xxviii, 95.

Epidemic Hicough.—Although a number of clinicians appear to regard this affection as *sui generis* Lhermitte looks upon it as one of the numerous manifestations of epidemic encephalitis. The term febrile hicough is understood, for a purely functional hicough with mass incidence might suggest psychogenic contagion. Many such episodes are found in literature (Briquet, Lasèque, Charcot). Boerhaave saw one in the Haarlem Hospital and one is known to have occurred in a Spanish convent. In the Middle Ages they would have been classed as demonopathies. The first observation of febrile epidemic hicough was made by Economo as part of an epidemic of encephalitis—not the original outbreak, but the myoclonic epidemic of the winter of 1919-20. So far as Austria was concerned the hicough antedated the encephalitis. The latter exhibited extensive polyclonic manifestations, including spasms of the diaphragm which recalled the original outbreak of isolated hicough. Economo was nevertheless very conservative in connecting the two manifestations—the idiopathic and symptomatic hicough. The same association of the two has been seen in Paris and Switzerland and the conclusion is hardly escapable that idiopathic hicough may be a monosymptomatic encephalitis. There are, however, differences hard to reconcile, for symptomatic hicough due to diaphragmatic spasm may be unilateral while true hicough is invariably bilateral. Here we see the germ of two separate manifestations, one a myopathy and the other neuropathic. In simple hicough there is no synergy save in the muscles which close the glottis, but in the symptomatic or myopathic form the abdominal muscles may be involved to some extent. The epidemic hicough as is well known is preceded by evidences of general infection of a mild type which is certainly not at all like epidemic encephalitis even in its mildest aspects. It may be termed epidemic febrile hicough and from analogy we could suspect the existence of a sporadic form. Not much is known of such and the only cases to come under this head are symptomatic of some severe and often lethal condition, while the recent epidemic cases are strikingly mild. The testimony of many observers clouds the subject, as when Ramsay Hunt stated that among many kinds of myoclonus seen in epidemic encephalitis hicough of any sort was notably absent. The author believes that in the interests of simplicity a unicistic hypothesis should obtain until there is some more definite evidence of dualism.

Le Progrès Médical.

November 27, 1920, xlviii, 48.

Anthropological Problems of Heredity.—Manouvrier discusses the "cross pull," so called, when a wolf is crossed with a dog and the hybrid inherits a double nature. The same phenomenon occurs in ordinary breeding of human beings and must be recognized in conjunction with environment in the personality of the subject. The author quotes a case in which a man of known sound stock for generations develops general paralysis. At that epoch it was not yet known that the latter can occur only in a syphilitic and hence the case seemed paradoxical. Today we know that the disease was acquired and hence the result of individual environment. It is true that a poorly bred horse cannot compete with a racehorse, but it is also true that very much can be done with a young colt in the way of training. The Lombrosian theory that both geniuses and criminals represent the innateness of a sort of psychic epilepsy has been entirely demolished. The segregation and sterilization of epileptics and certain criminals in the aim of extirpating criminality and epilepsy could be extended to include other classes of undesirables, but would this really abolish these classes of defectives? The ranks would be recruited from the results of traumatism, alcohol, syphilis, etc. We might learn as a result of this wholesale elimination of hereditary factors that postnatal factors were much more active than we had supposed. Such an experiment would no doubt be very instructive and the author does not antagonize it.

Le Progrès Médical.

December 18, 1921, xlviii, 51.

Puberty in the Abnormal.—Bancour of the Anthropological School says that a gap exists in our knowledge of puberty with reference to the prepuberal period, and again to the postpuberal. There are many individuals aged eighteen or thereabout who from the standpoint of puberal evolution are not over fifteen. He has devised a technique for rating these individuals. Godin has laid down formulae for normal puberty, the evidences of which comprise pilosity, voice change, deepening of scrotal color, and enlargement of the genitals. Hair appears in both the axillary and pubic regions; in other areas pilosity shows more variability and in evaluating puberty we must pay especial attention to the two regions just mentioned. Examinations for evolution of puberty should be made at least semiannually. In normal males, according to Godin, hair is first seen on the pubic region at fourteen and a half years on an average. Six months later the hair here will be found more developed, with the armpits still bare. In another half year the pubic hair will show further evolution, while a few hairs are to be seen in the axillæ or perhaps in only one of these hollows. At this juncture spermatozooids are present in the testes and ovulation has begun. This significance of axillary hair appears not to be generally known. The voice should have changed almost completely at this juncture, which is denoted by the formula P3 A1—meaning that the pubic hair has completed the second semiannual period, while the axillary hair is in its first six months' period. The subject is now fifteen and one half years of age. Physiological variation must be understood; for example, puberty occurs earlier on the average in the south of France than in the north, and normal puberty may appear at the age of ten in rare cases, and as late as seventeen. Among anomalous children there is much more precocious puberty than in the normal, but by the age of fourteen this departure has become more than offset. Delayed puberty is a matter of nutrition and not connected with anomalous individuals, with the exception of hypothyroid subjects. In the anomalous evolution of puberty seems more gradual and atypical, while pilosity is often more conspicuous. High degree idiots often show normal evolution of puberty. But the author's studies seem far from a satisfactory completion.

Le Progrès Médical.

December 25, 1920, xlviii, 52.

Severe Forms of Malta Fever.—Rozières regrets that this affection is still commonly believed to be benign.

Its mortality in Malta alone is said to be only 2 or 3 per cent. at the outside. This, however, is in selected material; even on the island the mortality in certain strata of the public amounts to 10 per cent., and if we study the records in outlying countries the mortality is seen to be high at times. In a series of fifteen cases in Algiers there were four deaths. The severity of the malady may be due to high temperature, extreme nervous depression, hemorrhage, various complications, etc. Among the latter are malaria, tuberculosis, and typhoid fever. Minor complications give the disease a more or less bizarre picture in individual cases; very much as in typhoid and malaria, in which the symptomatology by cases shows infinite variety. We may mention as complicating crises of sweating, obstinate constipation, pseudoappendicitis, pneumonia, empyema, myocarditis, simulation of acute leukemia, uremia (rare), orchitis—fortunately not followed by atrophy—abortion, bone and joint pains, meningismus, obstinate neuralgias, various rashes which simulate exanthems of infectious diseases, etc., etc. Severe cases and symptoms require appropriate treatment and vaccines, colloidal metals, autohemotherapy, salvarsan, etc., have all been used with more or less dubious results, as have also fixation abscess and autoserotherapy with blister fluid. Bad cases, in the author's opinion, are apt to be wrongly diagnosed; this naturally influences the mortality reports favorably. In all obscure deaths or doubtful illnesses the test for the *micrococcus melitensis* should always be practised, provided the disease exists in the locality or one near by.

Gazette hebdomadaire des sciences médicales de Bordeaux.

January 3, 1921, xlii, 1.

Diabetes in the Gravid Woman with Giant Cells in the Fetal Islets of Langerhans.—Anderodias and Dubreuil report this case. They first mention the two familiar types of glycosuria in the gravida, one of which preexists before conception, while the other appears during gestation. Both forms are rare enough. Leaving out of the question mild and transitory glycosuria, the authors have seen but two cases in twenty years in which the subjects were actually diabetic. In one of these the disease was present before conception. The child had been dead about eight days when the woman was delivered—at or near term. The other case was seen recently in a woman who was free from the disease except when gravid. In the first case there was no autopsy on the fetus. The second woman was a iii-para. Her first child had been still born, the second was living and well, and the third labor attended by the authors also ended in a still birth. On account of the immunity of the mother except when gravid a careful autopsy was made on the third fetus. Sugar had disappeared from the maternal urine somewhat slowly. The overlarge infant had a liver three times the normal size. The pancreas was the only organ studied under the microscope and the Langerhans islets were seen to be very large, although probably not more numerous than in the normal newborn. The volume of these islets was from twenty to thirty fold the normal. There must have been some connection between the size of the child—it weighed 5.5 kilos—the size of the liver, the state of the pancreas, and the maternal diabetes, but the author is unable to explain it. It has recently been shown that the fetuses of diabetic mothers are larger than normal. The tendency to still birth in these children may be due chiefly to the large size and resulting dystocia.

Remedy Against Hiccough.—According to Leven, the hiccough of aerophages, even when otherwise incoercible, will yield to lying prone and flat on the floor. Since the debut of the epidemic he has seen a case which had persisted 3 days, the nature of which he ignores. It yielded promptly to the postural treatment.—*La Presse Médicale.*

"El Siglo Médico."—Carlan, the editor of this well-known Spanish medical periodical announces the completion of the sixty-seventh year of its continuous existence. During this period it has striven successfully to maintain the dignity of science and of the medical profession of Spain.

Book Reviews.

THE DIAGNOSIS AND TREATMENT OF HEART DISEASE. Practical Points for Students and Practitioners. By E. M. BROCKBANK, M.D. (Vict.), F.R.C.P. Hon. Physician, Royal Infirmary, Manchester, Lecturer in Clinical Medicine, Dean of Clinical Instruction, University of Manchester. Fourth edition, with illustrations. New York: Paul B. Hoeber.

THE fact that this little volume has reached a fourth edition is evidence that it has proved of use to those for whom it was intended. It is, in the main, an introduction to auscultation of the heart; and medical students who are just beginning to grapple with this subject might find this little book serviceable when the larger works on the subject would only bewilder or repel them. The book concludes with a dozen pages on the treatment of cardiac disease.

BERETNING TIL INDENRIGSMINISTERIET OM RATIONERINGENS INDVIRKNING PAA SUNDHEDSTILSTANDEN VED M. HINDHEDE. Copenhagen: Jacob Lund, 1920.

THE Danish text of this pamphlet on the influence of the rationing of food on the health is made available by a ten page summary in English to the average American reader. Rationing was of course the immediate result of war conditions and as the general health of the community has been steadily improving for 30 years a falling off should be readily noticeable. The people received less protein, less animal protein, much less fat and alcohol, and in general less total food. The result of rationing was an enormous fall in the death rate due less to rationing *per se* than to reduction of consumption of alcohol and perhaps to a limited extent of tobacco and coffee. It has been shown that vegetable protein can fully maintain health. In regard to alcohol it is shown that it is much less harmful as a direct cause of disease than as a cause of lowered resistance to infection.

DIE BEHANDLUNG DER HAUT UND GESCHLECHTSKRANKHEITEN von Dr. ERICH HOFFMANN. Dritte, vermehrte Auflage. Bonn: A. Marcus & E. Weber, 1920.

THIS brochure of 167 pages is a very compressed compend of the subject which has reached its third edition in the space of three years and hence needs no encomiums. Seventy pages are devoted to dermatoses and 58 to affections of the sexual apparatus. To these sections is prefixed another on materia medica and pharmacy including apparatus for physical therapeutics. The arrangement of the material being alphabetical, the work is practically an index of treatment. The third edition gains by sections on a variety of new subjects, such as physical methods of treatment, salvarsan, masturbation, etc., etc.

PHYSIOLOGICAL CHEMISTRY. A Text-book and Manual for Students. By ALBERT P. MATHEWS, Ph.D., Professor of Biochemistry in the University of Cincinnati. Third Edition. Illustrated, New York: William Wood and Company, 1920.

WHEN one is reminded that the first edition of this valuable book appeared in September, 1915, and one reads, in the preface to the present edition, third, just five years later, that the practical part has been largely rewritten and many revisions made in the text because of the development of knowledge since the second edition was published in 1916, one realizes the rapidity with which physiological chemistry has advanced during the period covered by the World War. As might be inferred, the revision has been most extensive in the chapter which deals with vitamins. Part I deals with the chemistry of protoplasm and the cell. The successive chapters include a discussion of the general properties of living matter; the carbohydrates; the lipins, fats, oils, waxes, phosphatides, and sterols; the proteins; the physical chemistry of protoplasm. Part II deals with the mammalian body considered as a machine, its growth, maintenance, energy transformations, and waste substances. The chapters involve animal heat; the raw materials of foods; salivary digestion; digestion in the stomach; digestion in the intestine; absorption; the circulating tissue, the blood; the master tissue of the body, the brain; the contractile tissues,

muscle; the connective or supporting tissues, the bones, cartilage, teeth, connective tissue; the cryptorrhetic tissues, the thyroid, parathyroid, hypophysis, suprarenal, reproductive glands, pineal gland, thymus; the excretions of the body, urine; the metabolism of the body considered as a whole, carbohydrate metabolism; protein metabolism of body; metabolism under various conditions, vitamins, respiration, and conclusion. Part III, which deals with practical work and methods, includes chapters on equipment of the laboratory; quantitative analysis; the carbohydrates; the fats; the proteins; composition of the foods; salivary digestion; gastric digestion; intestinal indigestion; the blood; the urine. In many instances the discussion of the subject is followed by a comprehensive selected bibliography which should be useful to students who wish to do collateral reading. In addition to the general index of twenty-four pages, there is an index of practical works, and methods which serves as a quick reference aid in the laboratory. The volume, exclusive of the indices, embraces 1126 pages.

A HANDBOOK OF GYNECOLOGY, for the Student and General Practitioner. By BETHEL SOLOMONS, B.A., M.D. (Univ. Dub.), F.R.C.P.I. Gynecologist, Mercer's Hospital, Dublin; Consulting Gynecologist, Aut-Even Hospital, Kilkenny; Hon. Physician, St. Andrew's Ante-Natal Clinic; Formerly Assistant Master, Rotunda Hospital; Censor and Examiner, Royal College Physicians of Ireland, etc. New York: William Wood & Company, 1919.

IN accordance with the request of many of his students, the author has put his lecture notes into book form. There has been a certain amount of elaboration, but even at that, brevity and conciseness have been kept well to the fore. The book is designed for use in conjunction with hospital teaching and is well suited to this purpose; but the author seems overenthusiastic when he states that if a volume of this size (presumably meaning this volume) is read in conjunction with comprehensive teaching at a hospital there is no need for further knowledge except for the specialist. The text is written in rather free and easy style and much space is devoted to elementary matters. Most subjects are discussed very briefly, and the book is perhaps rather more suited to the student than to the general practitioner. Still, what the author has to say in regard to the various subjects is generally very much to the point, the main features in diagnosis and treatment are well brought out, and the practitioner will often find just what he needs here without taking time to consult larger works.

CONTRIBUCIÓN AL ESTUDIO DE LA AUTO-INTOXICACIÓN INTESTINAL. Por el Dr. CARLOS JIMÉNEZ DIAS, Profesor Clínico de la Facultad de Medicina de Madrid. Madrid: Ruiz Hermanos, 1920.

THIS little work of 142 pages is industriously compiled from many sources. The author's summary emphasizes the necessity of chemical analysis of stools, the unsatisfactory state of our knowledge of intestinal flora, the possibility of putrefactive changes without the presence of dietetic albumin, the formation of so-called putrefactive products by "dyspepsia, the double rôle of fatty acids as mere acids and as pathogenic substances, the erroneous teaching that certain urinary constituents are indexes of putrefaction, the plausibility of Herter's view that indol is a direct poison, the likelihood of abnormal absorption through which foreign protein can enter the blood and sensitize the organism, the part played in antioctoxication by mechanical distention of the colon, etc., etc.

LEITFADEN DER KINDERKRANKHEITEN FÜR STUDIERENDE UND AERZTE. Von Dr. WALTER BIRK, Vorstand der Universitäts-Kinderklinik in Tübingen. Bonn: A. Marcus & E. Webers Verlag, 1920.

THIS scientific treatise on the Diseases of Children has ten illustrations. While the etiology and pathology of the acute diseases of infancy are described the author elaborates on the symptoms, diagnosis, and treatment chiefly. There are interesting chapters on the heart, lungs, and blood disorders such as lymphatic leucemia. The chapters on the diseases of the brain are extremely interesting and up to date. Although very condensed, the book contains much valuable material.

Society Reports.

WESTERN SURGICAL ASSOCIATION.

Thirtieth Annual Meeting, Held at Los Angeles, California, December 3 and 4, 1920.

THE PRESIDENT, DR. ARTHUR T. MANN, MINNEAPOLIS,
IN THE CHAIR.

Control of Chronic Pain.—Dr. FREDERICK G. DYAS of Chicago said that injections of alcohol of varying strength had proved satisfactory in a large number of cases of facial neuralgia and had produced analgesia for periods of six to eighteen months. Thus, the efforts to short-circuit the painful area in facial neuralgia constituted the first accurate, scientific, and safe method of combating chronic pain. As the experimental and clinical data had not been sufficient to render an exhaustive report, the paper was presented rather as a preliminary study than as a complete work. Every surgeon had seen cases of malignancy in which apparently none of the older methods gave relief. The woman with recurrent carcinoma of the breast, for instance, rocking constantly to and fro with the pain, was not an uncommon patient in any large hospital. The dread picture was familiar to us all, and yet so far no work had been undertaken for its relief, apart from the use of morphine in ever increasing dosage. In many situations chronic pain might be controlled by interrupting the paths of pain conduction by the methods in vogue in local anesthesia. The scientific accurate control of pain would do much to rob the course of hopeless malignancy of its horrors. The mental anguish might remain, but the somatic suffering in most cases could be spared to the patient. The relief of constant pain revived the drooping spirits of the sufferer and enabled him often to put on weight and to gain in strength. The time honored, but inefficient attempts to produce euthanasia by the administration of ever increasing doses of opium or other narcotics must give place to a procedure which would be efficient and preserve the individual as himself to the end. The short-circuiting of the painful area was accomplished by nerve-blocking in the form of neurectomy or of intraneural injection. In relatively small superficial malignant lesions the same end might be accomplished by the healing of the ulcer by radium. This was especially true of lesions about the orifices of the body. Nerve-block relieved the pain during the period of healing. Chronic pain due to some condition other than malignancy was perhaps best treated by salt solution, novocain, apothemin, or quinine and urea, because these produced but temporary loss of pain conduction. In painful states due to malignancy in which loss of motor function was of little moment alcohol injections of the nerves or neurectomy was indicated. In cases of recurrent mammary carcinoma with great swelling and edema of the upper extremity, the patient usually had to carry the involved arm almost as a foreign body. Pain and swelling were so great that movement was practically impossible. Under such circumstances permanent block of the brachial plexus was indicated either by alcohol injection or by nerve resection.

Dr. JAMES F. PERCY of San Diego, Cal., stated that in his experience the extreme of physical suffering was to be found in the destruction of the pelvic bones by carcinoma in women. He had had a few cases in which the bony pelvis had practically fallen to pieces. This same thing occurred occasionally in the advanced types of prostatic carcinoma in men. He had never seen these cases sufficiently relieved by morphine. The only help for them, in his experience, was the epidural injection of some local anesthetic, usually novocain into the cauda equina.

Epidermoid Cysts.—Dr. H. H. SHERK of Pasadena, Cal., stated that epidermoids were evidently of fairly frequent occurrence, but almost invariably unrecognized. They were almost always mistaken for sebaceous cysts. They might be either traumatic or embryonic in origin. The pearly, horny, and laminated contents made their recognition easy.

A Group Plan for the Discussion and Description of Harelip and Cleft Palate Defect.—Dr. HARRY P. RITCHIE of St. Paul, Minn., said that, following con-

sultation with eminent authority on embryology and upon his own clinical experience and observation, he arrived at two leading conclusions: (1) Harelip and cleft palate were not two separate and distinct entities, but simply degrees of defect in the same embryological process of fusion. (2) The paramount anatomical situation affecting the surgical repair from all angles was the condition of the alveolar arch. Two subsidiary conclusions influencing to some degree his opinion on the technical features were: (1) Normally these tissues were closed from before backward. (2) The bones of the face in the newborn baby did not become fixed or rigid under an arbitrary period of three months. Therefore, if there were embryological data to prove that all of the many, many combinations were degrees of defect of the same process, was it not proper to speak of them as a part of the whole subject? Speaking and describing the various defects in groups seemed to him to be substantiated as follows: (1) They correlated the several conditions with embryological facts. (2) They separated the several conditions according to their special surgical requirements. (3) They defined strikingly, definitely and directly the important situation in the surgery of this defect—the condition of the alveolar arch. (4) They offered a very orderly plan for the discussion and communication with each other of our personal opinions in these age old problems of time and sequence of operation and technical details. In conclusion: (1) Each individual case should be immediately placed in one of four groups and degrees of defect in that group should be dispensed with as confusing and complicated. (2) If the surgical principles, as outlined in both lip and palate work were accepted, they permitted of a wide variation in technical details. (3) The constant clinical observation of the mechanical effect of the lip upon the tissue behind, in the third and fourth groups, he accepted as all important in indicating early operation. (4) Plasticity of the bones of the face held for three months, and in some cases longer, and this made early lip repair imperative. (5) The most reasonable basis of closure was to follow nature's path and form.

Dr. W. T. COUGHLIN of St. Louis stated that very few surgeons liked to do this kind of work. One had far better results in this work by closing layer by layer. In doing work on the face, where the wounds came through into the mouth, one got better results if he could approximate the mucous membranes without putting the stitch into the mouth. It was worth while in harelip to look for the muscle ends as they could be grasped and approximated.

Dr. C. D. LOCKWOOD of Pasadena, Cal., said he had followed the simple procedure of taking a pair of compasses and measuring the distance on both sides accurately from the location of the alae nasi to the junction of the skin with the mucous membrane on the lip margin. From this point another measurement was made on the mucous membrane. Exactly the same measurements were made on both margins of the harelip, whether it was single or double. The edges were freshened, connecting the points marked by the compass, and if these were accurately approximated one would get perfect union.

Empyema, Closed Treatment, with Films.—Dr. ARVINE E. MOZINGO of Indianapolis stated that for eighteen months he had charge of the empyema wards at the Walter Reed General Hospital and Base Hospital, Camp Pike, and developed an improved technique for the closed method. It was not definitely known who first treated empyema through a tube held air-tight in the chest wall with a view of maintaining negative pressure and preventing collapse of the lung. For years many attempts had been made to perfect such a method, but in most instances without success. He treated in the Army 138 cases, 45 acute and 93 chronic, with 2 deaths, both bilateral cases. He was able to follow up 80 per cent. of these cases and found no recurrence. Briefly, the method consisted in the introduction of a small rubber tube into the empyemic cavity by means of a straight trocar-cannula and the removal of the fluid with a bulb syringe. The tube was fixed air-tight in the chest wall and through it the secretions were removed from one to six times daily, followed by washing out with saline or Dakin's solution and later the injection of 2 per cent. formalin-glycerin.

This method was first described in detail in the *Journal of the American Medical Association*, December 21, 1918. It was also demonstrated by two reels of motion pictures which might be borrowed gratis by addressing Curator, Army Medical Museum, Washington, D. C. Most of the criticism he believed was offered to the closed methods in general. While the basic principles were much the same, the technique of each was decidedly different. The technique described by Lieutenant Die-drich came the nearest being like the one he described, yet it differed in many essential points. However, under him and later himself, there were 129 acute empyemas which had a trocar thoracotomy at Camp Pike. Of this great number 8 were transferred to another hospital and had a secondary operation. There were but 9 deaths, 7 during the influenza epidemic. Four of these 9 cases were bilateral and had they been uncomplicated and under normal conditions with plenty of help and room, they, too, in all probability, could have been saved. The question was often asked, was the drainage free, in the closed method? It was not free, for it was under absolute control. Neither was the drainage continuous, but intermittent, and the cavity under constant negative pressure. The secretion could be removed at will, and was usually removed once to three times daily, at intervals of from two to twenty-four hours according to the case. To prove conclusively that the cavity was completely emptied at each treatment a known number, say 5, 10 or 20 syringefuls of fluid was injected into the cavity. The process was reversed and invariably the same number of syringefuls would be removed, regardless of the position of the patient. He had never seen an empyema case too serious to be operated on by the closed method and could say that half of his series of 45 consecutive cases were operated on in the presence of an active pneumonia or some other serious complication.

Surgery of the Mediastinum.—Dr. ARNOLD SCHWYZER of St. Paul stated that purulent infections of the anterior mediastinum apart from direct trauma were mostly due to a breaking down of lymph glands or to the advance of an abscess which started in the neighborhood. Of these two conditions he saw one example. One was an abscess along the pericardium on the right side. It originated from a tuberculous chondritis of the fourth, fifth and sixth ribs. It had apparently started on the under surface. The abscess formed a narrow cavity of about 4 or 5 cm. depth along the pericardium. As tuberculous of the rib cartilage never healed when only the affected portion was removed, the whole of the affected cartilage was thoroughly excised. Iodoform was rubbed into the wound; the wound was closed up to a fine silkworm drain and healing occurred promptly. The second case was a lymph gland abscess taking its origin from what seemed to be one of the right pretracheobronchial glands. Poirier and Cuneo mentioned that the glands of this group, the pretracheobronchial glands of the right side were the most frequently affected ones among the pretracheobronchial group. The abscess in his case was located behind the second and third cartilages on the right side. After resecting these he entered the abscess cavity, at the depth of which (perhaps 5 or 6 cm. below the surface) a somewhat melanotic but principally chalcotic necrosed lymph gland of the size of a peeled almond was fished out. The patient was a stone mason, which explained the chalcosis. There was little organic matter left in the gland; it consisted principally of grayish grist. Healing after a few weeks took place. The case became doubly interesting when the patient returned about three years later with a similar condition on the other side. This time the abscess pointed in the sternal notch near the head of the left clavicle; and after incision he could enter an abscess cavity downward and inward behind the manubrium sterni, again about 5 cm. in depth. Again a necrotic mass came out, though only after about a week. It was a necrotic lymph gland of the anterior mediastinum, belonging to the group which lay in the angle of division of the superior vena cava into the two innominate veins, and which Bartels described as lymphoglandula anguli anonymi.

Movable Bodies in the Knee Joint.—Dr. O. F. LAMSON of Seattle, Wash., said that the picture of osteo-cartilaginous loose bodies was quite characteristic, as they presented themselves as well defined, uniform

shadows of individual structures. Dislocated semi-lunar cartilage would not give any x-ray evidence, except when incrustated. D-generated fat pads, due to chronic disease, such as tuberculosis and syphilis, might be palpated but x-ray would not reveal them. A sesamoid bone in the internal head of the gastrocnemius in certain positions might cast a shadow which could be mistaken for a loose body. Joint lipomata might cause locking, might be even felt, but would not have the characteristic picture of joint-mice. Attending physician's first duty was to relieve pain and locking and establish motion. With manipulation, forced flexion and sudden extension, the offending loose body might be usually dislodged. Surgery only would give lasting relief. If the treatment, as in most cases, was to be surgical, during operation the joint should be subjected to as little trauma and injury as possible, and more than the ordinary care should be taken to guard against infection. If the complete exposure of the joint was required, the longitudinal division of the patella might be imperative. But this procedure naturally entailed more injury to the joint than the safer longitudinal incision of the external surface of the joint. The diagonal incision following the internal line of the joint was preferable for the removal of the internal semilunar cartilage and other free bodies within the joint.

Dr. M. S. HENDERSON of Rochester, Minn., said that the chief point of interest in the paper was that the loose bodies in the case reported did not seem to have their origin from the internal condyle of the femur, but from the tibia. This was very unusual, and the only instance that he knew of such an origin of the body being demonstrable. Loose bodies in the knee joint were formed in various ways, and it was the study of their etiology that was particularly interesting. In certain individuals the bodies arose from the internal condyle of the femur, and he recognized this group as a definite clinical entity, giving it the name of osteochondritis dissecans. Marginal osteophytic growths found in hypertrophic arthritis broke off, wandered about the joint and nourished by the joint fluid increased in size, forming often many loose bodies. In still another group the bodies might be very considerable in number and on opening the joint it was perfectly clear that the bodies originated in the synovial membrane. This condition was called osteochondromatosis.

Dr. E. M. SALLA of Rock Island, Ill., reported a case similar to Dr. Lamson's several years ago in which there were 5 loose bodies in the knee joint. They were removed by open operation, and the knee was put at rest for six weeks with perfect restoration of the joint.

Dr. JOHN P. LORD of Omaha, spoke of one experience which he had had which he thought was of interest from different angles. A man, 30 years of age, presented himself fifteen years ago with one of these knees. The history was that of repeated locking, and the symptoms were so acute that the patient was laid up and disabled most of the time. He had seen several stiff knees following operations for the removal of loose bodies by operators who had worked through inadequate incisions, had spent much futile effort, and had infection follow. Therefore, he thought it better to make a free attack upon the joint rather than to undertake to make multiple incisions. A free transverse section was made including the patella, and clipping off some of these bodies which were attached anteriorly. The free access afforded by the ample exposure permitted the removal of the bodies in the condylar pouches. The largest of these bodies was one and three-quarters of an inch in diameter, and was doubtless formed by a section of the joint becoming detached.

Recurrent or Habitual Dislocation of the Shoulder.—Dr. M. S. HENDERSON of Rochester, Minn., stated that the essential factors involved in the mechanism whereby recurring dislocations might occur were considered. The primary dislocation caused a tear in the capsule in the weakest, most lax region; that is, at the anterior inferior portion. This area was not supported by the tendinous insertions of muscles, for the subcapularis was above it and the few fibers of the triceps that had their origin from the glenoid margin were below it. The supraspinatus and infraspinatus tendons might be torn at the first luxation and true tendon was always replaced by scar tissue which might stretch. The insertion of these might actually be torn off and relax-

tion and loss of tone of the muscles ensued, so that the head of the bone was just a trifle lower than it should be. When the arm was in the position in which most of the dislocations occurred, namely, abduction above the level of the glenoid fossa and slightly forward, the muscles and the direction of their pull were as follows: The supraspinatus and infraspinatus had not their normal tension, thus allowing the head of the bone to be a little lower than normal; the teres major, the latissimus dorsi and the pectoralis major all tended to pull the head into the glenoid fossa, but they also tended to pull the head downward and forward. The supporting action of the subscapularis was gone as the slightly abnormal low position of the head of the bone put the muscle on the upper half of the head of the bone in the position it now occupied. The head was thus thrust against the weak place in the capsule below the subscapularis and as the powerful latissimus dorsi, teres major, and pectoralis major contracted the head slipped on the edge of the glenoid margin and bulged out the capsule and glided up usually to be a subcoracoid dislocation. In the group under discussion, 23 in all, the average age was 28 years. There were 20 males and 3 females. They were equally divided as to sides. Trauma was mentioned as the initial cause in every case but one. There were but 2 epileptics; 19 patients were operated on, and 3 of these were so recent that they could not be classified as to results. This left 16 cases on which the statistics were based. The type of operation that had been used was capsulorrhaphy. Seven patients (43 per cent.) were cured; 4 patients (25 per cent.) were decidedly improved; that is, they had had very few dislocations since and were satisfied with the operation; 1 patient (6 per cent.) was improved; 3 operations (18 per cent.) were failures; and 1 patient (6 per cent.) was not traced. The first two groups of successful operations included 11 patients (68 per cent.).

Removal of Ventral Tumors of the Sacrum by the Posterior Route.—Dr. HERMAN E. PEARSE of Kansas City, Mo., said that these tumors interested the operating surgeon through the oddity of their origin and placement, the difficulty of their removal, and their dangerous habits of rapid growth and greedy encroachment upon bladder, bowel and ureter. They interested and puzzled the pathologist by the varied character of their cell formation and by the structural anomalies they presented. While a posterior incision with a sacral resection was an ideal way to reach these growths, it was practically impossible to do it supplementary to an abdominal incision. Rules of technique were outraged. The essentials of sacral resection for removal of tumors from the pelvis were: (1) The patient was placed on his face with pelvis well raised and thighs flexed. (2) An incision was made from just posterior to the anus upward in the middle line and carried above the coccyx; then curving to the left it followed the left edge of the sacrum. It was carried down to the bone and dissected outward right and left exposing the edges of the sacrum and the sacrosacral ligament, and carrying the edges of the gluteal muscle. (3) The third sacral nerves must be identified and the sacrum divided below them. They should, if possible, remain intact. The central canal of the sacrum should not be opened. The attachment of the sacrosacral ligament to the coccyx should then be severed; also the lower sacrum should be freed with a blunt dissector from all connections. The amputation was best done with a wire saw. The use of chisel and mallet here caused shock. (4) The field now lay before us. All bleeding was arrested and the growth attacked according to its location, attachment and adhesions. From this point the operation might be of any severity, usually it would be exceedingly simple. All Middlemord tumors should be attacked from this direction for the following reasons: (1) They lay directly in front of the sacrum. When it was lifted off they could be studied in plain view. (2) They could then be removed systematically without disturbing the remainder of the pelvic viscera. (3) The peritoneum was not opened in reaching the tumor. If it was opened later in the removal it was not traversed and infected, and its contents might be protected. (4) The cautery might be used freely without damage to other structures. (5) Extensive tissue removal in handling the tumor's connections in muscle, fat and fascia, even

bone, could be made quickly, safely and extensively because in plain sight. (6) Scar recurrence was in plain view and accessible to secondary operation. (7) Blood supply and nerve supply could be seen and easily attended to.

The Technique and Aftertreatment in Operations Upon the Prostate.—Dr. ARTHUR E. BENJAMIN of Minneapolis said that prostatic surgery had not reached the stage of perfection that was associated with other surgical work. The outcome was occasionally unsatisfactory on account of the indeterminate resistance of the patient and complicating conditions present. The functional results following certain types of operations upon the prostate were poor; there might be a stricture or a fistula. The mortality rate was relatively high for the suprapubic operation but the functional result and comfort of the patient had influenced most surgeons to adopt this method of operating. The function of the kidneys, the condition of the general health of the patient as well as the local infection should be treated before and subsequent to the operation. Every patient had a right to be in as good a condition as was possible before the operation was performed. Vaccine treatment sometimes assisted in overcoming infection. A special apparatus for doing the suprapubic operation made the second assistant of greater value to the operator, facilitated the work, and made it easier and more rapid in its execution. The technique resembled, in general, that of most operators who did the suprapubic work. A two-stage operation was seldom adopted. A double tube for drainage of the suprapubic wound was employed and a catheter was retained in the bladder by a suture passed through the internal end of the catheter and extending between the two suprapubic drainage tubes and there anchored. A normal convalescence by this method was more assured, infection less likely, and the comfort of the patient was greater.

Dr. N. J. MACLEAN of Winnipeg, Manitoba, said that some time ago he had 2 cases where there was stone formation in the bladder following prostatectomy. One case was passing small stones continuously with a great deal of discomfort and pain and the other case three years after the operation had the bladder filled with large stones, as large as small hen's eggs. The after-treatment was important. He might say that as far as the after-treatment was concerned, in his own practice he simply put in a large tube and after twenty-four hours aspirated the urine that was in the bladder and put in argyrol solution. This was left in the bladder and treatment was repeated once a day until the wound was closed. Since he had adopted this procedure he had not had postoperative stone formation.

Are We Getting Satisfactory Results in Stomach Surgery?—Dr. B. B. DAVIS of Omaha said that as the results now stood from 15 to 40 per cent. of the operations done for gastric ulcers were failures. At least, they did not restore the patient to sound health. There had been a tendency to explain the imperfect results on the ground that the operation was ill advised and the technique faulty. Moynihan asserted that many of the poor results following gastroenterostomy had been due to (1) operation done in the absence of any organic lesions justifying it; (2) in cases of chronic extragastric lesions that had been overlooked; (3) incomplete operation, the ulcer not having been dealt with, and (4) various defects in technique. The poor results following gastroenterostomies had too often, it seemed to him, been set down as due to faulty technique, to having been done in the absence of organic lesions justifying the operation, to incorrect diagnosis, etc., and apparently without considering that there might be some inherent fault in gastroenterostomy bound to be followed by many poor results, no matter how carefully the case was chosen or how technically perfect the operation. It was his opinion that active ulcers were better dealt with by excision or better still by cauterization, as so admirably worked out by Balfour. It was also important, when operating on ulcers, to find and remove the focus of infection from which the ulcers had their origin. The gall-bladder and appendix were always under suspicion and no operation was complete until these organs had been inspected carefully and removed if not normal.

Dr. F. M. SALA of Rock Island, Ill., said that it seemed the pictures shown by Dr. Davis were not taken

in a standing position. If the anastomosis was down at the ootom the stomach would empty immediately. The stomach dropped clear down into the pelvis normally in the standing position. If one was going to have a dumping stomach, he thought all pictures should be taken in a standing position to see where the anastomosis was. If the anastomosis was made as near to the pylorus as possible, its contents would have to go up nil, so to speak, and thus be a more natural process.

Dr. EDWARD C. MOORE of Los Angeles said that if we were all satisfied with gastroenterostomy, there would not be so many operations to correct this difficulty. Smithies reported a large number of cases of normal acidity in the stomach with ulcer. He hesitated very much to do a gastroenterostomy in duodenal ulcer in which there was no obstruction.

Dr. ARNOLD SCHWYZER of St. Paul stated that gastroenterostomy and the Finney method had advantages, but to decide which was preferable, one had to consider his own experience of years ago and go through it carefully. In the last fifteen years he had done about 140 stomach operations. There were many gastroenterostomies, and about 10 pyloroplasties. The results after pyloroplasty were not quite as good as the results of gastroenterostomy.

Dr. HERMAN E. PEARSE of Kansas City, Mo., said there were some facts to be considered in the study of gastroenterostomy and its end results. First, we must discount loyalty to the surgeon on the part of the patient. It was not enough that they reported themselves cured. We must get specific information as to vomiting, nausea, mixed eating, and body weight. Second, gastroenterostomy was not a drainage operation. The operation was most successful that placed the stomach at the point of greatest acidity where alkaline bile could relieve the acidity, whether it be near the pylorus or fundus.

Dr. ARVINE E. MOZINGO of Indianapolis, Ind., reported a stomach case which he saw five years ago in New York City. The patient was a man, aged 50, muscular, weight, 180 pounds, and general condition very good. He gave a history of having had a severe case of typhoid fever 21 years previously, complicated by ulceration of the esophagus resulting in complete obstruction. A gastrotomy was performed on him in Philadelphia and since that time all nourishment had been taken through a 1 cm. rubber tube 10 cm. long. The tube fitted snugly and was held in place by a large safety pin under which was a small gauze pad. A cork was held in the end of the tube by means of an abdominal binder. When a drink or food was desired, the cork was removed and a funnel inserted into which fluids were poured or in case of thick pasty foods they were forced into the stomach by means of a ramrod. Meats and other heavy foods were usually chewed, not only for mastication, but for the pleasure of taste and smell before being dropped into the funnel. The man would remove the tube about once each month to clean it. There was no irritation about the opening and no pain. The only discomfort experienced was due to the formation of gas at times and being unable to belch up this gas it became necessary to null the cork.

Who's Who in the Hospital?—Dr. H. G. WETHERILL of Denver said that all attempts to standardize hospitals and to establish in them scientific procedures, orderly methods and coordinated endeavor for the attainment of better results, must depend primarily upon the measure of success each hospital had in organizing and amalgamating the whole working force of the institution. In a closed hospital with a relatively small and carefully chosen staff of well trained and efficient medical men, such organization and standardization were easy of attainment and were to be expected as a natural consequence of the favorable factors presented. Careful case recording, laboratory facilities, autopsy study and coordinated diagnostic, therapeutic, and research methods should prevail. Unfortunately, there were comparatively few such hospitals in America, and of the open hospitals, only a relatively small number were so conducted as to be controlled or dominated by a group of highly trained and scientific men, even when such were available on the staff of the hospital. It was absolutely essential as a fundamental basis for progress along the lines of better hospital organization, which might some day lead to standardization, to first

control and govern this disassociated, irresponsible and unorganized element in the existing hospital system. It had been said many times that the standardization of hospitals and the standardization of physicians and surgeons must go hand in hand and that the advancement of one of these necessarily implied the progress of the other, but this could be true only if their interdependence was closely tied together and if consistent effort was made to bring within the fold all surgeons and all hospitals that presented evidence of qualifications that should entitle them to recognition. Once established, such a system would soon create for those hospitals and those surgeons who conformed to its requirements a prestige that would compel the compliance of all the others. The history of the reorganization of medical education in America would be repeated and the standardization of American hospitals would then be a readily solvable problem.

Laminectomy for Meningitis.—Dr. ROLAND HILL of St. Louis said that acute meningitis, especially when of streptococcus or of staphylococcus origin, was a very fatal disease. Netter, in a study of 65 cases, found that 54 died within four days. Death was the result of two factors, increased intracranial tension and toxemia. The first factor could be influenced by lessening the cerebrospinal fluid by means of lumbar puncture or by the establishment of open drainage. The factor of toxemia might possibly be influenced by the dilution of the toxins through the rapid secretion of cerebrospinal fluid. It had been his privilege to operate on 2 cases of meningitis with one recovery and one death. He believed in cases of meningitis from streptococcus or staphylococcus operation should be done. Whether or not it would be found advisable in those cases of meningitis following influenza seemed an open question. He had known a few of these cases to be operated upon, but had never known one to be operated upon early nor had he known a recovery to follow laminectomy in any of them. Recovery had followed repeated spinal puncture and it did seem only rational that laminectomy should yield infinitely better results than spinal puncture if operation was done before the cerebrospinal channels were blocked by inflammatory products or adhesions.

Section of the Anterolateral Tract of the Cord for the Relief of Intractable Pain Due to Spinal-Cord Lesions.—

Dr. W. E. LEIGHTON of St. Louis said that in this operation, as in all surgical procedures, a knowledge of the anatomy and physiology of the spinal cord was essential. The cord was exposed in the region of the fourth, fifth or sixth thoracic segment by the usual laminectomy; removal of two laminae were, as a rule, sufficient for proper exposure of the cord. The dura having been opened the dentate ligament was identified, grasped with a mosquito forceps and severed from the dura. Traction on this ligament would rotate the cord so that the anterolateral tract might be readily exposed. A small cataract knife with its back towards the dentate ligament was inserted just in front of the ligament and passed to a depth of two and one-half millimeters and brought out behind the origin of the anterior roots, making an incision approximately two and one-half millimeters deep by three millimeters wide. The section might be unilateral or bilateral, depending on the nature of the lesion. Bleeding was usually slight following the section. A stoveaine block might be employed previous to the section by placing a pledget of cotton saturated with 0.4 stoveaine solution on the cord above the level of the section. Following the section the dura was closed and the laminectomy wound sutured in layers. Following the operation careful nursing must be carried out as the patient had lost both pain and temperature sense if the operation had been correctly done, and the patient must also be warned of this particular. In all of his cases a hyperesthetic zone at the level of the divided segment had been noticed. Pain at this level might be so severe as to require an opiate to relieve it. From his experience in 4 cases, he believed it had been shown that the operation would produce a permanent relief in any lesion below the lower thoracic level. In the cases of gastric crises he believed that the section would have to be made much higher than the sixth thoracic segment, and saw no reason why it should not be made as high as the second or third thoracic. He would also suggest

to add section of all posterior nerve roots which were present in the field, as this would destroy sensory impulses which reached to a higher level and which were not touched in the section of the anterolateral columns, the site of section including only pain impulses which had crossed over to the spinothalamic tract below this level.

Splenectomy in Third Stage, Banti's Disease, with Report of Cases of Fifteen Months' Standing.—Dr. H. B. SWANERSON of Minneapolis said that splenectomy offered the best chance of recovery from the otherwise fatal terminal stage of splenomegaly. A plea was made for detailed histories of all cases of this type, subjected to splenectomy, and also for subsequent reports of progress at sufficiently late date after operation to determine the ultimate result as regards permanency of cure. Only in this way could judgment be formed as to the value of this procedure. In the study of the blood findings, it was not sufficient, from the standpoint of prognosis, to record the differential white count; a more intensive study of the cell structure itself was essential.

Fifth-Root Resection Under Local Anesthesia.—Dr. W. T. COUGHLIN of St. Louis said that the patient was operated on while sitting in a dental chair. A linear incision three and one-half to four inches long extended upward and backward from the zygoma a little more than the breadth of a thumb in front of the tragus. No transverse cut was made. The skin and underlying tissues along this line were infiltrated layer by layer. A similar infiltration was made along two lines parallel to this and about three-fourths to one inch from its beginning at the zygoma and ascending one and a half inches. The anesthesia used was one-half per cent. novocain with adrenalin six drops per ounce. If there was very much tenderness of the skin shaving was done the day before, the patient being morphinized for this purpose. It might be done the same morning, but not more than one-fourth grain of morphine should be given. The aponeurotic layer was incised along the upper margin of the zygoma from the incision each way for a distance of three-fourths to one inch; the fibers of the temporal muscle were split, as done by Abbe, and good retraction was made. The periosteum was scraped away from the surface of the squama and wing of the pterygoid. An opening was made low down with a burr as in Doyen's method which was enlarged to about the size of half a dollar. The dura was slowly separated from the bone by Tiffany's method. The middle meningeal was always tied before being cut. It was necessary to inject novocain around the region of the vessel before tying the artery. It was necessary to inject novocain into the third division before commencing to clean it; also to inject into the ganglion before opening its sheath. When the root was reached there was an escape of cerebrospinal fluid. The inner aspect of the dura at its opening around the root was very sensitive. Here a pledget of cotton soaked in 2 to 4 per cent. cocaine was laid for a minute or until one could proceed without causing pain. A hook was passed around the root without making any attempt to separate the sensory from the motor root and the operator might cut or avulse as best suited his fancy, since both seemed to give equally as good results.

Diseases of the Pancreas.—Dr. W. D. HAINES of Cincinnati said that growths in the pancreas had been successfully removed together with a large part of the gland. Coffey had devised a very ingenious method of providing drainage for the stump after resection by implanting it in an improvised pocket connected with the lumen of the intestine. Five pretty good sized arteries entered the gland. This and the intimate relation of an important anatomical structure rendered free exposure of the field of prime importance when one was operating. In a limited personal experience a long midline incision with division of the gastrocolic omentum had given a satisfactory exposure of the pancreas. If the stomach was prolapsed, one must either raise the organ to its usual position or expose the pancreas by dividing the gastrohepatic omentum. The former route was preferable when expedient, as it gave a far better exposure of the field. The greater peritoneal cavity should be protected during the operation, but if soiling had already taken place, ample provision for pelvic drainage must be made. Multiple

incisions of the gland employed for the relief of acute pancreatitis would be followed by considerable hemorrhage which might be controlled by gauze packing. Hietzler, in his excellent work on tumors, says: "Removal of tumor of the pancreas is technically possible but that it has met with little success."

The Report of a Case of Atresia of the Ileum with Microcoelia.—Dr. MARICE KAHN of Los Angeles stated that as to the genesis of this type of anomaly there was an unanimity of opinion. But not so of the stenosis and atresia, in which many theories had been advanced to explain their origin, viz., (1) Intrauterine volvulus. (2) Embolism or thrombosis of the superior mesenteric vessels. (3) Pressure from tumors or from amniotic bands. (4) Tracture of omphalomesenteric duct or its hyperinvolution. (5) Intrauterine peritonitis. (6) Persistence of the epithelium occlusion and ingrowth of the mesenchyma. In the case reported there was no evidence, such as twists, bands, agglutinated coils of intestine, etc., supporting any of the foregoing theories. It seemed to him that with the exception of the epithelium occlusion theory all the foregoing postulations might be discarded as more or less fanciful hypotheses unless post-mortem findings supplied the evidence. Moreover, there was assumed in the foregoing theories, excepting the last one, prenatal pathology, which was always a repellent explanation to the scientific investigator, whereas an evolutionary theory was attractive and respectfully entertained. Having recognized that the duodenal lumen in young embryos was normally completely obliterated by epithelium forming a solid cord of cells, Tandler concluded that sometimes this atresia might persist and be found as a congenital occlusion or stenosis. Forssner found that in early embryos the lumen of the duodenum was completely obliterated in places. This normal epithelium occlusion of the duodenum disappeared by a process of disintegration leading to vacuolation. Forssner thought that this epithelium occlusion might take place throughout the small intestine. Tandler considered that the cause of the occlusion was the resistance exerted upon the expanding epithelium by the surrounding mesenchyma. Moreover, when the epithelium occlusion was followed by sufficient ingrowth of mesenchyma, complete mesenchymal occlusion occurred and this condition might be permanent. Or by subsequent changes a stenosis might develop or valve formation occur.

A New and Advanced Surgical Treatment for Breast Cancer.—Dr. JAMES F. PERCY of San Diego advocated the use of the hot knife only in the surgery of breast cancer including the dissection of the axilla. In the advanced case he made no attempt to preserve or secure skin flaps and the edges of the denuded area left without flaps (when the breast and axillary glands are removed) should be undermined from two to four inches with the hot knife. In the after-treatment, besides the use of Dakin's solution the arm on the operated side was maintained in an elevated position with the forearm resting on the top of the head, until practically the surface denuded by the hot knife was entirely covered with new skin. As soon as granulations commenced to appear, vigorous daily massage and forcible movement of the skin and arm adjacent to the denuded area was instituted. The only carcinoma of the breast considered inoperable by the heat technique was the one where inaccessible metastasis had developed. The writer insisted further that the unheated knife did not devitalize any of the malignancy it did not remove. The hot knife did. The cold knife did not spoil the soil for the further development of cancer. The hot knife did. The knife unfortified with heat, if it touched cancer, vaccinated it into new areas. The hot knife did not. The cold knife stimulated the growth of the unremoved cancer cells. With the hot knife such stimulus was impossible.

Coexistence of Dermotropic and Neurotropic Syphilis in the Same Subject.—Brühl and two others presented a patient—a woman of 53—who showed typical tertiary syphilis of the skin involving the 4 limbs with intact and ulcerated gummata. At the same time there were speech disturbances, tremor, loss of memory and the general picture of pseudoparesis.—*Gazette des Hôpitaux*.

THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Held January 12, 1921.

THE PRESIDENT, DR. HERMAN B. ALLYN, IN THE CHAIR.

Occultism with Reference to Some Phases of Spiritualism and Freudianism.—Dr. CHARLES K. MILLS of Philadelphia presented this paper in which he discussed some of the alleged reasons for the revival of so-called occultism, holding that, while the sacrifice of life and the distress brought on families during the recent war might be regarded as important exciting causes, the whole matter could not be explained in that manner. Back of it was the tendency of the world to be largely controlled by instinct and emotion which had an immeasurable past. Dr. Mills gave his explanation, which he said might be only partial, of the reasons that not a few men of high accomplishment in science and scholarship had given their adhesion to modern spiritism, referring to Robert Hare, Sir William Crookes, Sir Oliver Lodge, Alfred Russell Wallace, Flammarion, and others. He said that these men in spite of their success in materialistic lines of research and writing were, after all, governed largely by their inherited temperaments in which instinct and emotion played an important part. He placed in the same list with Sir Oliver Lodge and others referred to, various men distinguished in medicine, law, and biology, who at the same time clung tenaciously to the tenets of some of the more primitive of the religious sects. Here the emotional temperaments held sway equally with or above the dominion of reasoning. The subjects of ghosts or apparitions, of mediumism and mediumistic communications were next considered by Dr. Mills. He expounded the view that stories of ghostly visitations, when these were not accounts of crude frauds or literary efforts, were best explained on the theory of hallucination. He held that most mediumistic exhortations were fraudulent, and gave accounts of some personal experiences with attempts at table tipping. Sir Oliver Lodge's "Raymond" received brief attention, the speaker pointing out the credulity of the author of the book, and the evident mistakes made by him in ranking many mediumistic communications as evidential. In concluding his paper Dr. Mills discussed some phases of Freudianism which he classed as a species of phallic mysticism. After defining Freudianism, he dwelt briefly upon what he regarded as unsuccessful attempts to apply some of its principles to both organic and functional nervous diseases. He did not attempt to traverse the whole subject of psychoanalysis, his paper simply being intended as an introduction to the symposium of the evening, leaving amplification and elaboration of the topic to those who were to follow him. He dwelt especially upon so-called transference neurosis and indicated some of the dangers which he believed threatened the community from the active pursuit and propaganda of Freudianism.

The Unconscious in Spirit Communications and Symbolism.—Dr. KNIGHT DUNLAP of Baltimore read this paper in which he said that the conviction, apparently shared by many spiritualistic mediums, that their communications came from outside themselves was based upon the common fact that in any fluent composition the verbal expressions tended to arrange themselves; that the formulated thought first appeared in the form of spoken or written discourse. This phenomenon might be observed by anyone who could compose fluently. The explanation that the formulating was done by the "unconscious mind" was misleading, since it was merely a reformulation of the problem: What was the mechanism by which this formulation was made? The true explanation was to be found in the analysis of thought as essentially a reaction process which, in these cases, was specifically a process of vocal reaction. The operation of the mechanism was then understandable in terms of the ordinary principles of habit formation, by which reaction tendencies were formed and modified by preceding reactions, based on hereditary predispositions existing within the nervous system. Experimental work on symbol recognition now in progress tended to indicate that this also might be explained completely by ordinary principles of habit formation, not requiring any assumption of an "unconscious mind"

other than the central nervous system. Training in symbolization was received by most persons through religious or literary channels, as well as by practical experience. Associations which had been formed in the past persisted as associations, without necessitating the persistence of any form of memory of the detailed experiences which formed the association, just as the ability to sign one's name persisted as a definite set of reaction tendencies without involving a retention of the detailed processes through which the child had gone in learning to write. The "unconscious mind" was a mystical concept quite comparable to the concept of divine agency in the production of thunder storms and tended to obstruct a scientific analysis of the question: How were the phenomena produced?

Dr. CHARLES W. BURR of Philadelphia said that Freud claimed that there was both a conscious and an unconscious mind. That one of the great functions of the unconscious mind was to keep out of our consciousness the things we wished, our real desires and wishes which were principally, usually, and most strongly sexual. This was done by a thing called a censor during waking life which kept out of consciousness the things that we consciously wished to keep out of consciousness, namely, our real desires. During sleep the censor ceased to act and the unconscious mind revealed itself in our dreams. A man then was what he really was, not in his waking hours, but during sleep. The dream with the unfulfilled wish, but when one dreamed he did not frankly and openly dream of what he wished; he did it symbolically. Every dream had a manifest content which was the dream as we knew it and the latent content, which was the real dream, and which could be found out only by the methods of symbolism à la Freud. Freud's book on "Dream Psychology" was sold in every department book shop in this country; it was bought by a tremendous number of adolescents seeking either for truth or unhealthy emotional excitement. This was doing them no good and it was not science. He wished to speak of something of much greater importance, namely, so-called communication with the dead. It was no new thing at all but was as old as the time when everybody was an atavistic worshipper and thought trees had souls. But now as time went on it seemed to him that mankind was pretty well split off into two great branches, the mystic and the rational. The mystic who hungered for a god and hungered for immortality. He had feelings and he believed what he craved. On the other side was the rationalist who was content with things as they were. The best subject for hypnotism was not the man of science whose mind was trained to believe what his experiments seemed to show. Because a man was great in one way did not indicate that his opinion in other matters was better than any of the rest of us. No one was so easily deceived as the man of science. In regard to communication with the dead we believed what we desired to believe.

Dr. J. HENDRIE LLOYD of Philadelphia said that the subject lent itself to the ridiculous, but lent itself still more completely to misunderstanding. It was the half educated poor in this country who believed in spiritualism, mysticism, occultism, and every other ism going on nowadays. It was the fault of our defective public educational system, so much lauded to the skies, which did not teach our children how to think, which left them the prey of any crank, half-baked religion, mysticism, or whatever you chose to call it. Now he had a theory that all of us were more or less superstitious. He, personally, did not believe in the superstition that if 13 sat down to a table one would die within a year, but the idea brought up unpleasant associations and, therefore, he did not like to sit down with 13 at a table.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held December 9, 1920.

DR. CHARLES HENDEE SMITH IN THE CHAIR.

The Tonsils and Scarlet Fever.—Dr. JESSE G. BULLOWA read this paper, which was based on a study of 153 cases of scarlet fever in respect to the size, covering, and compression of the tonsils, severity of the rash, and occurrence of lymph node involvement. He demon-

strated that the intensity of the rash did not affect the severity of the disease, but that it was very much aggravated by enlarged lymph nodes, which were due to infected tonsils and especially if they were covered and so swollen as to be compressed on swallowing. He also showed that of twenty-two asymmetrically diseased tonsils, six showed homolateral lymphadenitis involvement of the lymph nodes and that in sixteen tonsillectomized cases there was no adenitis, the disease was not severe, and there were no deaths, although some of them showed very severe rashes. He regarded the severe cervical adenitis as an epiphenomenon of scarlet fever which should be treated, though a phlegmon on the pharynx, as any other phlegmon. Tonsillectomy, when the tonsils were buried or covered with membrane, was a prophylactic against the severer septic forms of scarlet fever. Incision of the false membrane to relieve pressure, or in exceptional cases tonsillectomy was recommended.

Dr. HENRY KOPLIK said that scarlet fever, according to an eminent authority, Henoch, was a very insidious disease. It was a general infection, not an infection from any local point, but a general infection of the entire body, and not only were the glands and lymph nodes of the neck affected, but the glands and lymph nodes all over the body. In every case of scarlet fever the tonsils were involved more or less, so that this involvement became a diagnostic point of value, especially in mild cases or in those in which the rash was not well defined. A statement to make one think a great deal was that those cases of scarlet fever which were tonsillectomized did better than those which were not tonsillectomized. This might be true to a degree, but he could not forget those cases in which tonsillectomy had been done and in which scarlet fever assumed a most severe type, involving the throat and glands at the angle of the jaw, and not only that, but the tonsillar ring as well. If one looked at Sapp's anatomy he would see how interminable were the lymphatics of the throat and nose and would realize that by removing the tonsils only a very small part of the lymphatic structure of this region had been removed. In scarlet fever the whole lymphatic system was involved and therefore the removal of the tonsils did not absolve the throat from involvement if a child contracted scarlet fever. The same facts were true of grippé, angina, and diphtheria. The fact that a child had had his tonsils removed did not prevent him from contracting angina, diphtheria, or scarlet fever. Dr. Koplik cited the case of a boy subject to periodical attacks of angina, who had his tonsils most skilfully removed, and he still continued to have the attacks after the tonsils were taken out. He had seen many of these cases. Those who dilated on the advantages of tonsillectomy as a prophylactic measure should not forget these cases. It was nothing new to take out the tonsils during scarlet fever. He was glad the subject had been brought up, because it was desirable to work it out further. Personally he was rather backward in adopting such heroic measures, though he knew they had been employed and employed successfully in certain cases. There were a great many cases of scarlet fever in patients with necrotic tonsils, suppurating adenitis, otitis media, and even necrotic bone in the mastoid, and the latter often did well with simple incision and drainage. In other words, scarlet fever was not a disease which enabled one to draw conclusions, and the reader of this paper, very wisely, had drawn no conclusions; but we should not forget the severe cases that did well without tonsillectomy. There were cases in which the tonsils were not involved to any extent in which at the end of ten days or two weeks a tonsillitis with adenitis developed and the patient went through a very severe illness, accompanied by suppuration of the glands and disease of the tonsils and other complications, all after the tonsils had been judged to be well. The principal objection to tonsillectomy during scarlet fever was that it opened up a large field for the absorption of bacterial toxins, and it was a question whether one was justified in doing that. We should not forget that there were many cases in which tonsillectomy was done and death ensued.

Dr. CHARLES HENDEE SMITH described a case which was under his care last winter which illustrated one or two of the points Dr. Bullowa had made. This

child had had a bad throat, large tonsils, and a rather acute scarlet fever. On the sixth day an adenitis developed with a great deal of swelling of the glands. The temperature subsided and then went up. The case was somewhat puzzling for a time until it was discovered that the child had mumps as well as scarlet fever. It was learned that the child had been exposed to mumps just seventeen days before the trouble began. The case was interesting from the fact that there were three sets of glands involved, some of the glands being as large as a walnut. He had seen the child six months later and all the glands had disappeared.

Dr. ROBERT J. WILSON said that when Dr. Bullowa first proposed this investigation he told him he might carry it out if the parents gave their consent to the tonsillectomies and if, in his judgment, he was going to do more good than harm. Dr. Wilson said he had watched these cases with interest and of one thing he was sure, namely, that they could not apply this procedure as a routine proposition. He would simply say that if in the surgeon's good judgment it looked like a case that could be operated upon and the local condition in the particular patient indicated it, then it was all right for the surgeon to go ahead. There was no doubt that some remarkably favorable conditions followed operation, and he had seen exactly the same thing when no operation had been done. He did not mean that Dr. Bullowa's and Dr. Crawford's judgment was not good, for it was, but in all these innovations it was understood that they were not used as routine measures. Dr. Koplik had put it well when he said that this was a contribution and that one should go slowly with things of this kind. So far as the health department side of this work was concerned, when the Willard Parker, the Kingston Avenue, Riverside or other department hospitals turned out a piece of work of this kind it was for the purpose of making physicians think, but it was not intended that such things were to be adopted indiscriminately in every case.

Dr. BULLOWA, in closing the discussion, said that scarlet fever, if there was such a disease, and some even questioned it, had been described as a disease with a general lymphadenitis, and Dr. Koplik had emphasized that point. However, the point of view might be presented that the large palpable lymph nodes were a response to the inflammatory involvement of the skin. He had observed that where the rash was slight or took a peculiar distribution, the enlargement of the lymph nodes was not symmetrical, and that where there was the most rash there one found the largest lymph nodes. The point that the involvement of Waldeyer's ring and the adenoids was an important factor needed no emphasis. He had emphasized in the paper that it was the rhythmic pressure which was responsible for the forcing of the toxins into the lymphatic system, and the same thing might occur with the adenoids if they were so large that they pressed against the structures on the posterior surface of the maxilla. Of course the proposal of tonsillectomy in scarlatina was not original or new. Similar work had been done in Boston by Dr. Place, who reported twelve cases operated upon in the acute stage. It was work that could not be done by the family doctor or a general surgeon, but must be done by a dexterous operator, for the operation had to be done quickly and had to be clean cut behind the capsule, so that there would be no wide opening up of the lymphatics. As to the question of operating in the acute stage of scarlet fever, in the army there was a large number of cases of streptococcus infection of the tonsils which were operated upon successfully in the acute stage. Of course cases got better in spite of a long drawn out illness, but in the group of five cases there was one case, which was operated upon and got better, the others did not get better. Dr. Bullowa said he was not proud of the statistics for scarlet fever in the Willard Parker Hospital, a mortality of 7.2 per cent. in his series and more than 8 per cent. in all cases for five years seemed too large and any procedure that promised to reduce that mortality was worth trying out.

Precocious Puberty.—Dr. MARK S. REUBEN presented this contribution, based upon a study of seven personal cases and 390 cases reported in the literature. He stated that precocious puberty was not a distinct entity; it might be due to various causes; the symptoms

varied with the causes. An attempt was made to differentiate the various types clinically from a study of all cases that came to autopsy or operation. Of the 397 cases studied, 326 were females and 71 males; of these there were 188 females and 57 males in whom definite etiological factors were lacking. In 23 cases there were tumors of the ovary; in nine cases (eight females and one male) there was hyperplasia of the adrenals, or adrenal rests; in 21 cases there were tumors of the adrenals (17 females and four males); in seven cases there were tumors of the pineal (all males); in one case there was a tumor of the testicle and in one case a tumor of the prostate with metastases in the testicle. In 83 cases precocious puberty was associated with precocious pregnancy. In females menstruation was the first symptom of precocious puberty; it might be present at birth; at first it might be irregular, and might have molimina. The breasts were usually enlarged in all cases; the external and internal genitals showed marked development. Hair was usually present on the genitals and in the axilla. The voice deepened and there was a lengthened physical growth, but owing to premature ossification there was no tendency to gigantism; on the contrary, at the time of real puberty these individuals were somewhat undersized for their age. In most cases this was accompanied by an increase in muscular power and in adipose tissue. There was broadening of the pelvis. Dentition in a number of cases was early. Onanism was present in only a few cases; early sexual desire was usually not present. Mentality usually corresponded to the real age, though a few were precocious. In the males erections and ejaculations took place; physical development was marked; they became very muscular, athletic, and strong. The secondary sexual characteristics made their appearance. In 15 males the mentality was normal, in 15 deficient, and in four precocious. Libido was increased in a few. In case of precocious puberty due to tumor of the ovary, menstruation was always present; the external and internal genitals were always enlarged; pubic and axillary hair were always present; the breasts were enlarged in 75 per cent. of the cases, and in 90 per cent. of the cases the mentality was normal. In cases due to tumors of the adrenals there was a tendency to produce maleness in the females and to exaggerate maleness in the males. The internal genitals were usually not enlarged; the external genitals usually showed enlargement of the male type in females (enlargement of the clitoris); the breasts did not enlarge, and menstruation was usually not present; there was a tendency to growth of a beard in females, and to overgrowth of genital, axillary, and general bodily hair growth. There was marked tendency to adiposity; in 70 per cent. of the cases there was mental backwardness. This condition was far more common in females. Tumors of the pineal gland were more common in males; both external and internal (testicles) genitals were enlarged; there was pubic and axillary hair growth; these individuals all showed marked adiposity and all had manifested cerebral symptoms. In 80 per cent. of the cases mentality was normal and in 10 per cent. it was precocious. In one case of precocious puberty due to tumor of the testicle the genitals were enlarged; there was general hair growth and marked physical development. After removal of the testicle there was complete reversion to childishness. Of the 84 cases of early pregnancy associated with precocious puberty the ages at the time of delivery were as follows: in one case six years; in one case seven years; in three cases eight to nine years; in five between nine and 10 years; in six between 10 and 11 years; in 14 between 11 and 12 years; in 54 cases between 12 and 15 years. Labor was easy in 22 cases; normal in five cases; difficult in nine; instrumental in five; complications were present in eight cases; 14 infants and three mothers died during delivery. Of 27 infants whose sex was mentioned 13 were males and 14 females. Of 37 infants, 20 weighed over seven pounds at birth.

Dr. SMITH ELY JELLIFFE said that it might not be inappropos to say something of Pellizzi's syndrome of precocious genital development, particularly in relation to defective pineal activity, since the speaker had raised the question of its possible relationship to hypopituitarism from hydrops of the infundibulum. In a series of cases reported with Dr. Bailey of pineal tumors

they had referred the adiposis so frequently seen in the pineal syndrome—Fröehlich cases—to the hydrops of the infundibulum and the cutting off of the nerve pathways to and from the hypophysis as they traversed the hypophyseal stalk. This interference with vegetative stimuli to or from the hypophysis was probably the cause of the faulty metabolic disturbance. The precocious sexual development, however, was a different affair and probably, as Marburg had suggested, a pure pineal syndrome. Pellizzi had erected his syndrome, however, solely on clinical grounds. He had no autopsy material. He later, through the work of Poà and Sarteschi in his laboratory, sought to give it an experimental foundation. Dr. Jelliffe referred to the recent work of Boehme (*Frankfurter Zeitschrift für Pathologie*, Vol. 22, 1919), who had recapitulated the evidence concerning pineal deficiency and early sexual maturity, and had furthermore described some entirely new findings which if further corroborated would be of considerable interest. In a teratoma of the pineal gland with precocious sexual development he had observed cells closely resembling the interstitial testicular cells of Leydig. These, if functioning early, might either directly or through gonadal interaction, be held to be the responsible factor in the precocious sexual development.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

ON THE RESPONSIBILITY OF THE GENERAL PRACTITIONER IN REGARD TO CANCER.*

By L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK.

SENIOR PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, ETC.

CANCER if left entirely to itself may be said to be always fatal; the rare exceptions prove the rule. According to surgical authorities the mortality of those once affected with cancer (excluding cutaneous epithelioma) is 90 per cent., under present modes of treatment. It is well recognized that the death rate has been steadily and alarmingly rising of late years in the United States, and almost everywhere, during the last 20 years certainly; and in New York City during the week ending December 4, 1920, there were 121 deaths recorded from cancer, or more than 17 per day, even more than from tuberculosis. In New York City the recorded deaths from cancer, from July 1 to December 31, 1920, were 2,691, and those from tuberculosis 2,669, or 22 less than from cancer.

It may seem a strange thing to assert, but really the general practitioner is largely responsible for this sad mortality from this dread disease.

By great medical effort on the part of the profession at large, with great personal attention and skill of certain medical men, the mortality from tuberculosis has been reduced almost 30 per cent. since the year 1900, whereas by turning the disease over largely to the surgeons, the death rate from cancer has increased almost 30 per cent., as much as that of tuberculosis has diminished, during this same period. Is it not, therefore, time to stop and consider if this *ignoring* of cancer by physicians has not resulted from *ignorance* of its true nature, and if the *neglect* of the study of the medical aspects of the disease has not resulted in a *negligence* which is not wholly excusable?

All recognize that the early detection of tuberculosis is a most important element in connection with its treatment and cure, and surgeons have long and strenuously urged that the early diagnosis of cancer is most important, if there is to be any hope at all in regard to its successful surgical treatment; for they all acknowledge that fully one-half of all cases (some say 75 to 80 per cent.) come to them too late to expect any real and permanent benefit from the knife. If the surgical aspect of this is true, as is doubtful in the light of the ex-

perience of those who have seen the multitudes of recurrent cases, even after very early operations, it is particularly true in regard to the medical treatment of cancer: for when the disease has lasted a long time, and when there are already many metastases, each contributing to the further poisoning of the system, and especially in recurrences after surgical operations, the medical cure of the disease is most difficult. But happily even in these distressing, inoperable, and recurrent cases very much can be accomplished by the use of careful, patient, and prolonged medical measures, as experience abundantly shows.

Now the general practitioner sees patients both with tuberculous disease and with cancer in their earliest stages, indeed the family physician sees and knows his patient long before any possible physical manifestation of either disease reveals itself to the sight or touch; and if he is on the look-out for cancer as well as tuberculosis, and knows the condition of system or the habits of the patient leading up to either, he certainly can ward off a very considerable proportion of both diseases. For it is to be remembered that the definite lesions, afterwards recognized as cancer or tuberculosis, are but the *result of product* of a preceding, long continued error in life, a culmination of faulty living which it is his duty to discover and overcome. The mass which we call cancer is but the departure of previously normal body cells, slowly augmenting in number until it is recognizable by sight, touch, or otherwise. The mass has not developed in a day or a week, but begins with a single cell or cells, which have renounced their allegiance to normal body control, and instead of performing their normal functions or producing homologous tissue, have broken away and gone on an erratic and destructive course, forming heterologous tissue, possibly for months; this latter tissue is not only of no use to the system but tends to break down, and the process thus once started tends to continue, and, with the unchecked errors of system which first started the diseased process, it commonly proves ultimately fatal. Some one has likened the whole thing to a mutiny in an army or on shipboard, beginning with one or two persons, who, resenting a faulty quality or quantity of food were able to make the discontent spread, until large numbers were similarly infected and great harm resulted, until the errors in nutrition were rectified.

There need be no mystery in regard to cancer. Everything has a definite cause and cancer is no exception. It is no extraordinary or sudden invasion by some occult outside agency. All ob-

*Address before the Lehigh Valley Medical Association, January 13, 1921.

servers are agreed that it is *not* parasitic and that it is *not* contagious; no surgeon, nurse, or pathologist, coming in contact with cancerous tissue has ever been infected. But the accumulating evidence all points to an endogenous cause, resulting from systemic errors, even as are gout, arteriosclerosis, rickets, obesity, and many other maladies, which are more or less successfully met and overcome, without our being able to point to any one single cause for any of them.

The real cancer problem, therefore, is to discover and rectify in each individual the wrong elements of life which lead up to the faulty condition of the blood current, which should supply such perfect nutrition to all the cells composing the body that none of them will want to go astray and pursue an abnormal, wild, and destructive course, like soldiers who have mutinied against improper or insufficient rations; for the "blood is the life," and if exactly the proper blood is furnished, with exactly the proper elements of nutrition, correctly elaborated by the various organs of the body, including the endocrinous glands, all the cells of the body, being properly nourished by it, will perform their functions and not have cause to rebel. If any have already rebelled they can be brought to allegiance by careful attention to their wants, by diet, hygiene, and proper medication, and even masses which have been formed can be dissipated and disintegrated and absorbed; just as pleuritic effusions, arthritic deposits, and rickety changes can be dissipated by proper remedial measures, equally well with the callus formed around fractured bones.

The responsibility of the general practitioner in regard to cancer, therefore, lies along several lines. Great emphasis has been laid by the surgeons upon the very early recognition of the disease when there have already developed lesions which can be recognized by the sight or touch. This is undoubtedly most important, but I would stress the point that he should do more than this. As a family physician he should know his patients so thoroughly that he can foresee when they are drifting toward the cancer maelstrom, by their habits of life, overeating or eating wrongly, self indulgence, indolence, etc. For it has been clearly shown that cancer is more than *twice* as prevalent among the well-to-do, self-indulgent, and indolent class in the richer districts of London than among the general average in the whole land. While cancer has been shown *not* to be hereditary, there is no question but that if cancer has been prevalent in a family, the same customs or habits of life, which have been more or less handed down, can and will sometimes cause the disease to occur in descendants.

Time does not permit of detailing as fully as might be desired the exact elements leading toward cancer which are to be looked for and remedied or modified by the family physician; these have been developed more or less fully in other writings, but some mention may be made of them with advantage.

Cancer and tuberculosis stand at the opposite ends of nutrition. Tuberculosis subjects are as a rule underfed or poorly nourished and overworked, while cancer subjects are as a rule overfed and underworked. Even Ewing, in his nas-

terly work on neoplastic diseases, repeatedly speaks of cancer cells as being overnourished, while many clinicians have called attention to overfeeding and improper food as, at least, a contributory cause of cancer. Very many during the past hundred years have alluded to this, and especially to overindulgence in protein foods. And in regard to both of these, long experience has taught me that this is abundantly true. For years I have treated innumerable cases of cancer, often with marvelous results, with an absolutely vegetarian diet and other measures, some patients for years continuously.

Constipation, or imperfect intestinal excretion, is an almost universal condition in cancer patients, and unquestionably has a most important bearing on the disease, so much so that some observers reckon that colonic infection plays a great part in the depreciation of the blood leading up to cancer, which I most strongly endorse.

Urinary derangements, or deficiency in regard to the excretion of proper solid constituents in proportion to the body weight of the individual, also play a most important part in the causation of cancer. Repeatedly I have found them not one-half the amount called for by the patient's weight, and age and as the cancer has improved under the treatment given the urinary secretion has returned to its normal proportion of solid elements. Time does not permit of an elaboration of this point, or a description of the technical details in carrying out the study, which have been repeatedly dwelt upon in writing. The matter is not difficult to carry out, but it is a little tedious and troublesome to watch the daily output of urine, as I have often had done for weeks or months, and in some cases for several years.

The saliva, which has so much to do with digestion, is constantly found at fault, being acid instead of alkaline, both in early and late cancer, and in the hospital, especially, I have had it tested and recorded 15 minutes before and 15 minutes after eating, over long periods. As the disease improves under proper medical treatment the reaction changes and becomes normal, if one can succeed in getting the patient to carry out proper and prolonged mastication. This latter is a most important feature in carrying out the medical cure of cancer, as indicated on the diet card, which every patient has to follow exactly.

Overeating and erroneous eating have been mentioned as elements in the causation and continuance of cancer, and this matter must be sedulously looked into and controlled by the family physician, both before the full development of a cancerous lesion, and long afterwards, even after a surgical operation. x-rays, radium, etc.

The protein intake has a very important relation to the development and continuance of cancer, and some reviewers of my books, as also medical writers, have connected my name solely with a non-meat diet as a cure for cancer; the error of this is readily seen from what has preceded. But that animal protein has a great deal to do with the genesis and continuation of cancer there is no doubt, as I have repeatedly shown statistically and clinically. But protein is necessary for the formation of the cell and its nucleus, and animals secure

sufficient protein from the vegetable kingdom, and so can man, as do many tribes and nations, and hosts of vegetarians in civilized life. On the other hand excess of animal protein causes many ills, as all are aware, and statistics show that cancer has increased in many regions proportionally to the increase in the consumption of meat, while it is almost unknown where meat is not used. The family physician can, therefore, aid greatly in the diminution of the morbidity as also the mortality of cancer.

When for any reason cancer has become developed, so as to show a neoplastic tumor anywhere, the general practitioner has still a very great responsibility.

Heretofore the single thought of the physician has been to consult with or turn the patient entirely over to a surgeon, according to the still prevalent idea that an operation affords the only possible hope for such a case. But the general physician, being the family adviser has to decide whether to counsel the patient or friends to take the chances of operative removal, which thus far has failed to check the rising mortality, which surgeons agree attends 90 per cent. of all cases once affected, or to advise careful and complete medical treatment, which shows a very much lower mortality, and with far greater comfort to the patient. A Swiss physician, Dr. Aebli, made a study of a large number of operative cases with an equal number of those not operated on, and found that the average length of life in the former did not exceed that in the latter, although these latter did not have any special medical treatment, only general care by family physicians. Dr. Ewing, in his purely scientific book on neoplastic diseases states that from his large observation, as a pathologist, secondary operations on recurrent cases shorten life, while we all know that the pain attending cancer recurring after operative procedures is commonly most distressing.

It is a little curious that the surgeon, because he is a surgeon, whatever his experience may be, is supposed to know all about cancer, and that these cases belong exclusively to him. No one honors the surgeon, and the wonderful advances he has made in certain lines of surgery, more than the present writer, but as a rule the surgeon does not generally think along constitutional and metabolic lines, but confines his attention largely to the knife and more recently also to x-rays and radium, all of which attack only the *local products* of the disease cancer; while the constitutional condition, which first produced the local lesion is left unchanged, and pretty certainly will reproduce the neoplastic growth in or near the original site or elsewhere, partly by metastasis. Over one hundred years ago the celebrated English surgeon, Dr. Abernethy, remarked, in his classical book on tumors, as follows: "There can be no subject which I think more likely to interest the mind of the surgeon than that of an endeavor to amend and alter the state of the cancerous constitution. The best timed and best conducted operation brings with it nothing but disgrace, if the diseased propensities of the constitution are active and powerful. It is after an operation that, in my opinion we are most particularly incited to regulate the constitution, lest the disease should be revived or renewed by

its disturbance." And from then down to the present time many physicians and surgeons of prominence, whom I have elsewhere quoted, have, often in very strong language, declared emphatically a similar belief. But all these brave and forcible expressions seem to have been overlooked, forgotten, or ignored by the medical profession in recent years.

As I have already said it is the general practitioner who has to decide, which course it is best for the patient to pursue, and although his advice may not be followed, owing to the glamour of surgery and its often spectacular results, and the almost universal belief of the laity, guided by common medical and surgical opinion, he at least can feel that he has done his duty.

If happily he has advised an anti-operative course, and the advice has been followed, he has now a still greater responsibility. For unless a proper medical course is accurately followed out with great assiduity, patience, and perseverance, and over a very long time, months or even years, the disease will not yield entirely and the patient remain free from the threatening calamity. Even as in tuberculosis, the course of treatment must be exact and rigidly carried out for a length of time, or there will be a recrudescence, should the patient return to the same physical conditions of life as before; for instance if he should live in damp, unhealthy quarters, avoid fresh air, eat wrongly, etc.

Time does not allow our dwelling long on the various elements which enter into the medical cure of cancer, which have been elaborated more or less fully in my books and other writings, but I may say that there is nothing in them which an intelligent, educated, earnest, and patient general practitioner cannot carry out successfully, if those qualities are really put into the conduct of the case. I do not, of course, mean to imply that any one can check or cure all cases of cancer, for cancer has baffled the profession for years and certainly in many it will be already too far advanced, or they seem to have too strong a tendency to the disease to have it yield readily to even the most careful treatment. But from long experience I am firmly convinced that if the general practitioner were to take up in earnest the study of cancer, and could and would apply sufficient acumen, diligence, and patience in regard to the necessary details of treatment, such as have been indicated here and elsewhere, he would in the average show a far lower rate of mortality than at present obtains throughout this and other countries.

The first requisite for a successful carrying out of the medical treatment of cancer is to have a firm and fixed belief in the propositions which have been presented here and elsewhere. There must be so great a confidence in it that he will not be discouraged either at complete failures in certain cases, or at unfavorable turns in others, but must always be ready and able to meet emergencies and to seek out where the error in treatment lies, and try to rectify it. For, as before remarked, everything has a cause, and cancer is no exception.

The next requisite is that he must be so persuaded in his own mind of the correctness of the theory and plan of treatment that he can convince

and satisfy the patient that he or she is pursuing absolutely the best course, and although the disease is reckoned as a desperate one, that a faithful pursuance of a proper course offers the best hope of ultimate recovery, or at least the best chance of prolonging life and escaping pain; this I have shown by many undoubted cases of cancer in various locations. For the patient will undoubtedly be beset by many friends, as well as physicians and surgeons who will stoutly claim the contrary; some of my patients after recovery have told me that they suffered more from this cause than from the disease or its treatment.

It will unquestionably be difficult in many cases to hold the patient faithful to this line of treatment over a sufficient length of time to effect the best results. They must understand the difference between the single, seemingly brilliant result of a surgical excision, with its too commonly unfavorable ultimate results, and the slow, patient effort to remove the basic cause of the disease and induce absorption or internal disintegration of the offending mass. Some will weary of the dietary and hygienic restrictions, and of the long-continued taking of the necessary remedies, and certain of my patients have yielded to the solicitation of friends and medical men, and have undergone operation, which I have often heard them regret afterwards.

The physician must see to it that every necessary detail of treatment is faithfully and accurately carried out. To accomplish this great care and patience must be exercised at each interview, which should be rather frequent, to inquire particularly into every detail, often by cross questioning; for the average person is unaccustomed to consider small details of absolute importance, and many get weary and careless in following out routine treatment in such a chronic disease as tuberculosis or cancer.

I think it is best for the patient to know that he or she has cancer (although there may be exceptions) and understand so fully from the beginning, and to be reminded frequently that the success of medical treatment depends very largely upon himself. Ordinarily in this disease the patient expects the surgeon to do everything, and the surgeon is so accustomed to leaving nature to heal the wounds he has made, or to unite the broken bones he has set and protected, that he does not have thought sufficient in regard to the correction of the elements of life which have to do with such a disease as cancer. For it must ever be borne in mind, as already mentioned, that the diseased mass, which we call cancer, is only the *product* of a previous long-continued error of the system, which if allowed to continue will pretty certainly continue to produce similar lesions elsewhere, however frequently they may be removed surgically. It is quite as unreasonable to expect otherwise as to expect that the excision of a gouty toe, or a late syphilitic tumor, or a tuberculous joint would result in a perfect and permanent cure, if nothing more were done for the patient than the operation.

From all that has been said it can be readily understood that the too common custom of only watching a patient with a developing cancer, before instituting a medical or surgical cure, or do-

ing the same after a surgical operation, or the use of x-rays or radium, is a most serious and fatal mistake. Every day passed is lost time and endangers the ultimate success in the case, for when carcinosis is once fully established the true, basic cause of the disease increases with almost geometric rapidity.

It is true that in thus attacking the earliest suspected manifestations of cancer we may sometimes be dealing only with a relatively innocent condition, such as adenoma or mastitis in the breast, or an ulcer of the stomach or a chronic dyspeptic condition which might end in true cancer, or stone in the urinary or gall bladder, or fecal impaction somewhere in the intestine, all of which if not rectified may lead up to cancer.

Mention has been made of x-ray and radium, toward which the attention of every one is now directed in the vain hope that in them may be found the cure for cancer, and as the general practitioner always seems to suggest these, since the results of surgery have been shown to be so unsatisfactory as to the end results, a few words in regard to them may not be out of place.

The x-ray is certainly of great value in the cure of epithelioma of the skin, if properly used, and I have employed it very satisfactorily in scores or even hundreds of cases. Radium is also very effective in these cases, but is out of reach of most patients. Radium also has been reported on most favorably, by certain skilled experts with large supplies of the same, in certain cases of cancer of mucous surfaces, on the lip, tongue, inner cheek, and cervix uteri. But for cancer of deep organs little if anything can be done with this agent. Personally I have had little experience with it, but have seen many cases where it has been tried in vain, and also some patients who are loud in their attestations that the disease has been much worse since it was tried, and many cases of very serious and rebellious burns from x-ray and radium have come under my observation and treatment. The x-ray is lauded by many physicians and surgeons as an adjunct to surgery, both before and after operative procedure, and as of value in checking and removing metastatic deposits in lymph glands. But it is a delusion to trust to either x-ray or radium in real internal cancer; their action is but local, like surgery, possibly causing a local lesion to diminish or disappear, but they cannot affect favorably the basic, constitutional causes of the disease, and so cannot effect a cure.

In regard to the various suggestions and trials of different forms of serotherapy, which have been presented and vaunted, often by able and conscientious physicians, as well as by quacks, a few words may be said. To my mind there is an error in supposing that one or many injections of a foreign substance can ever reach the real cause of cancer, or so affect the system that a continuance of the evils which have produced the disease will not cause a recurrence of the same local manifestations, and will not in the end prove fatal. The great variety and different characters of these injections which have been suggested, tried, and failed, is indeed disheartening, and shows that a real cure cannot be expected along these lines.

Glandular extracts rest on an entirely different

basis, for the endocrinous or ductless glands undoubtedly play an important part in the mechanism and physiology of the system, and it may be possible that at some time we may learn just how they affect the condition of the blood, and may be able to utilize an extract of them in the control of cancer. We know already that there are some diseases in which disorder of ductless glands is implicated: such are myxedema and cretinism with the thyroid, Addison's disease and high blood pressure with the adrenals, and gigantism or acromegaly, due to disorder of the pituitary gland. Thyroid extract, when properly used, has already been shown to be of value in cancer. But, as before remarked, even a short course of any of these agencies cannot possibly be permanently effective if the dietetic and other causes of cancer are allowed to continue unchecked.

We have thus seen that the general practitioner has very much responsibility in regard to cancer, in all its stages, and even before it really begins. It has been seen how thoroughly wrong it is to ignore the disease, and to regard it as hopeless, and to shift at once the responsibility upon the surgeon, who does the best he knows how, and attacks the product of the disease with the knife, x-ray, or radium, but who, as a rule, does nothing to check the real basic cause of the same.

It is also seen how wrong it is to tamper with cancer, and only to wait and watch until it can be decided to let the surgeon have his sway, for surgeons all tell us that at least one-half of the cases come to them too late to expect any lasting benefit from an operation.

The family physician, therefore, should have charge of the patient from the moment that there is any suspicion or suggestion from any source that cancer threatens. Patient, careful investigation of the patient's life in every respect will commonly reveal errors of life, or even beginnings of disease of various kinds, including tuberculosis and cancer. This watchful care should be continued until it is assured that the danger of cancer has passed, and if perchance a tumor has developed the watchful family physician should hold on to the constitutional treatment, by dietary, hygienic, and medical measures until either all is dissipated or the patient succumbs to the poison. For even in the latest stages a very thorough medical course of treatment is of value, so that life may end gently and peaceably without a particle of morphine or other anodyne, as I have repeatedly witnessed. Indeed, as I look back upon my experience in private and hospital practice I am sure that those patients who have taken morphine have suffered altogether far more than those who have not had it, for they did not require it if every detail of treatment was properly carried out. Morphine certainly checks the secretions and interferes with the action of the endocrinous glands, and thus increases the very errors which cause the neoplasm, keep it in existence, and cause pain; for cancer, if undisturbed, is not as a rule the terribly painful affection which it is commonly thought to be.

Time does not permit us to dwell longer on this most interesting subject, or to detail all the elements which go to make up the correct internal and local management of these cases, which have

been fully considered in other writings. But in closing I wish to emphasize as strongly as possible the responsibility of the general practitioner in regard to taking up seriously the study of this disease and its medical treatment, for cancer has long been really a disgrace to the medical profession. It is hardly conceivable that the profession would for so long a time tolerate the practice and treatment of any other disease which showed such a steady and lamentable rise in mortality as has cancer, namely, nearly 30 per cent. since 1900, while that of tuberculosis, under careful medical guidance has fallen nearly 30 per cent. in the same length of time.

10 EAST SIXTY-FIRST STREET.

EARLY AND IMPORTANT SYMPTOMS OF MENTAL DISEASES.*

By MAX H. BOCHROCH, M.D.

PHILADELPHIA, PA.

VISITING PHYSICIAN TO THE PSYCHOPATHIC DEPARTMENT OF THE PHILADELPHIA GENERAL HOSPITAL, ETC.

THE question is constantly occurring to the mind of the thinking physician: "Is insanity on the increase?" Just as we ask ourselves: "Is syphilis on the increase?" The press, and indeed, journals of all kinds have discussed the question, and, in most instances, in an intelligent and fairminded manner. Statistics have been brought into play, in most instances the articles have been fair, just and stimulating to the reader—to both professional and lay minds. The writers usually adopt the theory that the apparent increase is due to the ability of our profession to recognize either of the above diseases in their incipency and with more accuracy than formerly.

The stigma which formerly rested upon the unfortunate one who had lost her or his reason has become modified to some degree, and the cases, under these circumstances, are more apt to come under the notice of the public. This appears to be the more conspicuous reason given by the authors for the seeming increase of insanity. However, the poor and sick we have always with us. I do not intend to discuss the war psychoses, the subject of shell shock, the gassed, etc. In discussing the subject of the increase of insanity, the war, its effect upon the ones who remained, waited, and watched, and the new conditions of life, the economies which had to be practised by many, and the extravagances indulged in by others, not forgetting the radical change in women's attire and its effect upon the susceptibilities of some of the male sex—all this bears upon the question of the increase of insanity.

Even when the diagnosis of insanity is made early by the general practitioner or the family physician (I use the terms synonymously), or in consultation with the neurologist, there is no easy road to recovery. The persistency with which the general practitioner still relegates his cases of hysteria and neurasthenia to the scrap heap for undiagnosed functional nervous diseases, is appalling. It is to avoid this humiliating and grievous error that I am addressing you this evening.

*Read before the St. Joseph's Hospital Clinical Society.

With the exception of the insanities which accompany or follow infectious diseases, alcoholism, and those following operations and epilepsy, it may be stated as a principle that insanities come on slowly.

Let us take up first that most important disease, dementia precox, recently also termed "schizophrenia"—meaning a splitting up. I know of no disease in general medicine more important, more interesting, or more fascinating. Presenting innumerable phases to the physician, but only to him who wishes to do serious thinking, it is equally, if not more important than tuberculosis or cancer. Dementia precox lasts for years. None are cured; about 10 per cent. in private practice reach an apparently normal level. These unfortunates constitute 20 per cent. of all cases admitted to institutions for disease of the mind. The economic questions involved, therefore, may be readily understood.

The disease develops in young, educated, attractive persons. In the female illegitimate pregnancy or sex perversions are common. It is no respecter of the rich or poor. It occurs most frequently in young adults who are advanced educationally. The early symptoms of this disease, leading up to the most pronounced symptom, are confusion, listlessness, more or less apathy, difficulty in concentrating on studies or work, inability to concentrate on the matter in hand; a certain amount of antagonism is developed towards those formerly loved and respected; there is a tendency to secretiveness—the patients do not wish to seek their former friends and companions. The female who was formerly the personification of modesty will become erotic. She will lie abed far beyond the accustomed hour, and it is difficult to get her up. If observed closely, her movements suggest eroticism. She may be practising masturbation. Both male and female subjects soon show inability to keep up with their studies; application to study and concentration become increasingly difficult; they fall behind and soon give up the pursuit of education. In the male a change of occupation without adequate reason should be looked upon with suspicion.

How can one confuse this picture with hysteria or neurasthenia? There are no attacks excepting in rare cases of crying or laughing. There are no palsies and no anesthetics. Neurasthenia is a fatigue neurosis. Neither time nor occasion permits me to discuss Babinski's theory in relation to these latter diseases.

During the prodromal period of dementia precox the patients may be very much depressed at times, indeed suicide is not uncommon. How often do we read in the lay press of suicides of young persons where the reason is not even suspected. These patients also complain of somatic symptoms; of indigestion, abdominal pains, palpitation of the heart, etc., etc., and I regret to be compelled to state that many an unwarranted operation has been performed by my gynecologic friends on these pitiful subjects. The disease progresses steadily. The symptoms enumerated in the foregoing now become so pronounced that the patient's attitude and conduct become so peculiar that medical aid is sought.

Let us review the earliest symptoms of this disease. An indifference to the ordinary routine of life, whether it be school or occupation, curious antagonism to a parent, brother, sister, or devoted friends. Important events or incidents are treated in a light-hearted manner. A death, a serious accident, any calamity, will be related by the patient accompanied by silly behavior or laughter (paramimia).

To the trained observer—and nothing tends to train the mind more accurately than watching the bizarre symptoms of a case of dementia precox—it will be noticed soon that the patient is somewhat confused. Indeed, confusion is one of the earliest and most important symptoms. Hallucinations of hearing are considered by some distinguished authorities as pathognomonic of dementia precox. It would be better to say that we should look with suspicion upon a diagnosis of dementia precox without hallucinations of hearing. Nevertheless, I have seen cases of dementia precox without hallucinations of hearing. Visual hallucinations are not so common. In the beginning of this disease the patient hears noises not voices in his ears. Singing, roaring, whistling, buzzing, "simple noises." But as the case advances the patient hears voices; she hears voices calling her by name. The voices may command her to do things, to commit suicide. They may pertain to simple subjects but they more often pertain to disgusting and obscene matters.

You will remember that I mentioned among these curious and bizarre symptoms of this complex disease, antagonism. If this particular symptom is carefully analyzed you will find that it often partakes of the nature of "negativism," as it is technically termed. In other words, the patient, instead of following a request or a command, will do just the opposite. If you ask him to open the mouth, he will close it. If you ask him to stand up, he will sit down, etc. It is true that this is not always one of the earliest symptoms, and it is supposed to respond to the hallucination of hearing, which instructs the patient to do otherwise than as commanded. Katatonia, or waxy flexibility, is another symptom, like so many others which appear later, and which in this paper I cannot dwell upon.

A test of the greatest significance in deciding upon an early diagnosis of dementia precox is the Aberdalen, or a modification of it, called the sex-gland reaction. Dr. E. Corson White has carried on this test for me, for years, and in a great number of cases. All the ductless glands of the body are examined; a specific and typical reaction of the sex glands is obtained. That is, in the male, the testicles react in a certain manner, and in the female, the ovaries. Not once has Dr. White failed me in the correct interpretation of the diagnosis. Where the sex-gland reaction could not be obtained, the cases invariably proved not to be dementia precox. I want to take this opportunity to express my gratitude to Dr. White for her splendid work and in the examination of many patients without pecuniary reward.

Following the lead of Kraepelin, and to make a general survey of the psychic, clinical picture of dementia precox, attention is called to two prin-

cial groups of disorders which characterize the malady. On the one hand we observe a weakening of those emotional activities which permanently form the mainsprings of volition. In connection with this, mental activity and instinct for occupation become mute. The result of this part of the morbid process is emotional dulness, failure of mental activities, loss of mastery over volition, of endeavor and of ability for independent action. The essence of personality is thereby destroyed, the best and most precious part of its being, as Greisinger once expressed it, is "torn from her." It is worthy of note in any case that memory and acquired mental proficiency may occasionally be preserved in a surprising way when there is complete and final destruction of the personality itself.

The second group of disorders, which gives dementia precox its peculiar stamp has been examined in detail especially by Stransky. It consists in the loss of the inner unity of the activities of intellect, emotion, and volition in themselves and among one another. Bleuler describes them as incoherence of the train of thought, in the sharp change of moods as well as in the desultoriness and derailment in practical work. But further, the near connection between thinking and feeling, between deliberation and emotional activity on the one hand, and practical work on the other, is more or less lost. Emotions do not correspond to ideas. The patients laugh and weep without recognizable cause, without any relation to their circumstance and their experience. They smile while they narrate the tale of their attempts at suicide. They are very much pleased that they chatter so foolishly and must remain in the institution permanently; on the most insignificant occasion they fall into violent terror or outbursts of rage, and then immediately into a neighing laugh. It is just this disagreement between the idea and emotion that gives their behavior the stamp of silliness.

The next psychosis to which I would call attention is manic-depressive insanity, closely related to dementia precox. Indeed, in dementia precox we sometimes meet with a manic-depressive phase, and in the early stages the diagnosis is often extremely difficult. It would be much easier to describe this disorder and to give you case histories after it has reached its full development, than to limit myself to the early symptoms. Manic-depressive insanity may range from the mild form of hypomania to the more pronounced forms of acute mania and delirious mania. We have in these cases emotional exaltation, flight of ideas and psychomotor excitement. In the depressive phase it may range from simple retardation to the more pronounced forms of acute melancholia and depressive stupor, emotional depression, difficulty in thinking and psychomotor retardation. We also have a mixed phase, in which we have a combination of manic and depressive symptoms, as agitated depression.

By circular insanity we mean when one phase is followed immediately by another phase.

How many of us are not subject to episodes of exaltation and depression. Of course, in normals these conditions are occasioned by environment,

endogenous states, very frequently the colon bacillus. A brisk purge, a good walk, a pleasant piece of news, and, after all is said and done, a healthy constitution, and we are ourselves again. But those with a constitutional taint are not so fortunate. The depression, accompanied by psychomotor inactivity, persists. The depression may last for days, weeks, or even months. Or it will be succeeded by exaltation, just the reverse of a depression. These cycles are irregular, they follow no rule. Exaltation may precede the depression. Which may last the longer, the depression or the exaltation?—that again follows no law. If the depression reaches the depth of a melancholia, or the excitement of a mania, you would not need a description of the disease. We are constantly surrounded by persons who are suffering with prolonged depression. Then we have that interesting individual, the hypomaniac, who builds cities, railroads, and churches. It is true that it is only when this individual commits some overt act that he comes under the observation of the physician or under the ban of the law. Psychomotor activity, mentally exaggerated, cock-sure of themselves—many successful business and professional men are hypomaniacs. If you have the privilege of examining these persons over a long period of time, you will find that they have their periods of depression, and that during this particular period their life work frequently proves a failure.

I have related to you concisely the early symptoms of two of the affective psychoses, dementia precox and manic-depressive insanity. I shall not pursue the psychoses further, but take up that most interesting and much written about disease—parietic dementia, general paralysis of the insane, or dementia paralytica, a disease which destroys the mental functions and deteriorates the entire physical organism. If recognized in its earliest stages, the disease can be arrested, perhaps cured. At least, the patient's life may be prolonged, and he may continue a useful existence. When the disease has progressed beyond the initial stage, arrest is difficult, if not impossible. In the fully developed stage, treatment is absolutely futile. The patient often becomes a burden to his family, or a ward of the county or State. At the present time we do not hear so much about the prodromal or pre-parietic stage, the fully developed disease and the terminal stage. This is due to the advent of the Wassermann test, which is of such tremendous importance in the diagnosis of all syphilitic diseases.

Why some syphilitic individuals develop paresis and others do not is still an interesting and mooted question. It is supposed that the highly neurotic individual is prone to paresis. The Hebbrews were at one time supposed to be comparatively free from paresis, but this is no longer true. They are afflicted in relative proportion. Is it possible that a laxity of their traditional family life, and what this implies, with their highly organized nervous system, has been the cause of the appearance of paresis in due proportion among them? Ireland was at one time thought to be almost free from paresis, but this, also, is no longer true, owing, I believe, to closer

observation and more accurate diagnosis. Kraft-Ebing maintained years ago that the predisposition to paresis is acquired and not hereditary. The African race is exceedingly liable to paresis. The disease is more common among males than females. Paresis is much more common among the lower than the higher class of females. It is most common between the ages of thirty and fifty years; it is infrequent after sixty years. An important factor relating to the time at which paresis manifests itself is the wear and tear to which the patient has been subjected. At or about middle life, when the stress of life in most people is about the greatest, and the resistance is on the wane, the toxin of syphilis, or the spirochete itself, which up to this time may have been dormant, awakens to activity and to destruction. Whether there is a special strain of the spirochete, which causes paresis, and another tabes, is another intensely interesting question, which is now under investigation. Paretics live at most from three to five years. They generally grow fat. Tabetics live for years and die of some intercurrent disease. In other words, great and persistent business and professional worries, disappointments and overexertion, trauma to the head—all may be considered exciting causes. Alcohol, it is needless for me to say, does not cause paresis, but early paretics become tipplers on account of an unaccountable depression. A man who formerly did not know the meaning of the word fatigue soon becomes tired. He notices that he is unable to perform the same amount of mental and physical work that he formerly did with ease. His staying powers become greatly lessened. Concentration becomes a positive burden. Sleepfulness is an early and most valuable symptom. Business men will fall asleep during most important conferences, board meetings, etc. Gradually it is noted that the patient not only lacks his former alertness in grasping and dealing with the difficult problems of the day, but he fails to grasp and forgets about the ordinary matters of daily life. The man with a system becomes careless, even reckless; the fastidious man becomes untidy; he forgets to arrange his clothing properly when it is imperative that he should. Table manners, formerly correct, become woefully lacking. It seems a trifling matter to speak of, but suspect the former particular man who appears before you with the evidence of his dinner on his waistcoat. A looseness and carelessness of speech becomes apparent; a distinct laxity of morals in a person who previously lived an exemplary life; excessive venery in a certain type of paretic is quite common. A complete change of character is sometimes perceptible. A degree of abandon sometimes occurs in the moral and business life of these patients that is appalling. Homes and fortunes have been wrecked. If time and space permitted, I could recite cases that would astonish you and that you would think almost unbelievable. We have in these cases everything from blunting of the emotions to moral degradation.

Please bear in mind that I am dwelling upon the earliest symptoms, before a division into the expansive or the depressed form can be made.

Now leaving what might be called the mental picture of this disease in its very earliest stages, what are some of the physical stigmata? By far the most important single symptom is the appearance of the pupil. Even in its earliest stages, the pupil undergoes changes. It may be fixed, responding only sluggishly to light or to accommodation. It may be unequal in size and not respond to light or accommodation; or again it may be irregular in outline, ovoid or egg shaped. In some cases, we have an Argyll-Robertson pupil. Do not infer from what I have said that this form of pupil means dementia paralytica, but it means a syphilitic pupil, and a syphilitic pupil, with the mental symptoms which I have described, would lead one at once to think of paresis. An irregular, or unequal pupil should be considered a syphilitic pupil until otherwise proved. Attacks, epileptic in character, frequently occur. They may occur with or without convulsive seizures. In other words, they may resemble fainting spells. The knee-jerks in the early stages are generally exaggerated. Careful examination of the tongue reveals a fine tremor, involving the muscles of that organ. A fine tremor of the muscles of the face, near and around the labio-facial fold, when the mouth is stretched wide open, can frequently be detected. Early and inexplicable fatigue, in contrast with former vigor, comes at the end of the day. Neurasthenics become active in the evening. Change of disposition or character—indifference to the niceties of life; impaired judgment; ideas of self-importance; exaltation, and, last of all, ideas of grandeur, combined with pupillary changes and a positive Wassermann reaction—these symptoms, I repeat, should make one give an exceedingly guarded prognosis.

My paper is perhaps already too long. I am aware that it contains nothing original. All that I have said can be found in many textbooks. If, however, I have brought some facts to your attention, each one of considerable importance, and with some deeper hidden significance than a mere mention may expose, if, I repeat, these facts have attracted your attention to these "subjects" whom we have always with us, then my work has been a pleasure.

1539 PINE STREET.

THE CRIMINAL.

BY PERRY M. LICHTENSTEIN, M.D., LL.B.

NEW YORK.

PHYSICIAN TO CITY PRISON, MANHATTAN (TOMBS); PHYSICIAN TO HOUSE OF DETENTION, ETC.

AN ounce of prevention is better than a pound of cure. This is an old adage and a true one. Effort has been made to apply this principle to various conditions and subjects, including also the field of criminology, but owing to faulty theories and false methods, we have not been very successful in preventing crime. We can never hope to do away with crime entirely. That would obviously be an impossibility, but we can reduce crime to a minimum by seeking the cause and eliminating it. It is easy enough to keep a person in jail and see that he serves his term, but we have so far

found it rather difficult to create the moral and legal atmosphere which will bring the commission of crime down to a minimum.

Let us see what enters into the etiology of crime at the present time. What type of individual is the criminal? Shall we idolize him, as has been done recently or shall we treat him more sanely, taking into consideration his mental and physical condition and its probable relation to the criminal act of which the prisoner stands accused? Is there any definite classification of prisoners? I shall attempt to answer these questions.

At present I have found criminals composed of the following classes: Drug addicts, 20 per cent.; mental defectives, 20 per cent.; insane, 1 to 2 per cent. The remaining 58 or 59 per cent. are composed of prisoners whose criminal record and tendency may be directly traced to environment, opportunity, and temptation, and finally heredity.

It will be noted that drug addiction heads the list. This is so because at present addiction is greatly on the increase and is helping to fill our jails. Recently it was the practice of certain physicians to prescribe morphine, heorine, or cocaine, for a certain consideration. No honest effort was made to reduce the patient. The rapidity of reduction depended solely upon the resources of the patient. If the patient had sufficient means he could obtain as much of the drug as he desired. If he was poor, well, he was "out of luck" and had to suffer. In order to satisfy his craving he committed crimes so as to obtain sufficient money with which to purchase the drug. The fact that it is a crime to steal did not enter into consideration. The single desire uppermost in the addict's mind was to obtain the drug. In addition to prescribing morphine or heroine, the physician also prescribed cocaine, thereby fastening another habit on the individual.

At present there are few physicians indulging in this practice. This is due partly to the fact that several have been sent to prison by the Federal authorities, but mainly to the fact that enormous quantities of the drugs are being smuggled into this State and country, and that the same is being peddled by certain individuals who reap enormous profits. Commissioner Enright of the Police Department has recently appointed Dr. Carlton Simon as a Special Deputy, the sole idea being to solve the drug problem. There is no doubt that this is a wonderful step in the right direction, but with the laws as they exist at present, I fear that arrests will have but little effect in reaching a satisfactory ultimate result. We must have a new Federal law. At present the State and Federal laws governing narcotics conflict. The Board of Health rulings conflict with both these laws. There is, therefore, chaos. Commissioner James A. Hamilton and the author have for some time advocated the following law. Dr. Frank A. McGuire of the City Prison also advocates this law. It will be seen from the following that we advocate hospital treatment for the addict, followed by proper methods for rehabilitation and finally probation. There must be a total prohibition of the drug excepting for medicinal purposes. The following is the law advocated:

1. All narcotic drugs and their derivatives coming into the United States to be placed under the supervision of the United States Public Health Service.
2. The United States Public Health Service is to sell or dispense these drugs to the State Health Service of each State, record to be kept of same.
3. The State Health Service is to sell or dispense the drugs to the Board of Health of each city, record being kept of same.
4. The Board of Health to have stations in each district, open day and night, at which places physicians and druggists may obtain the drugs, a record being kept of same.
5. The establishment of dispensaries or receiving stations, where addicts may apply for treatment without fear of arrest and from which place they may be sent to certain designated hospitals to take the treatment.
6. The establishment of farms to which these addicts may be sent after being taken off the drug, and where they can remain for at least six months. Then to be placed on probation for at least two years and made to report once a month for examination; then to be returned to treatment if found that readmission has occurred.

If such a law is enacted it will do away with addiction as a cause of crime. The punishment can not be made too severe for those who sell or distribute the drug. The author wishes to state that in his opinion more has been accomplished recently in handling the drug situation than has been the case in any previous city administration. We must eliminate addiction as a cause of crime for in doing so we will be reducing crime approximately 20 per cent.

Mental defectiveness is another contributing factor in the production of crime. A mental defective is a potential criminal. He is easily led. He is susceptible to suggestion and seems to assimilate all that is bad and to reject all that is good. He differs in the main from the normal individual in that he thinks after he acts whereas the normal individual thinks before he acts. The defective, in other words, lacks judgment, and this is quite apparent to his associates of the criminal type, for they seize upon this weakness as displayed by word and actions of the defective, and make him their tool in the commission of crime. Investigation has shown that at least 20 per cent. of individuals coming to the City Prison (Tombs) are mental defectives. This is exclusive of drug addicts, many of whom are also mental defectives. How shall we remedy this condition? To answer this question is quite difficult. We cannot compel every individual to submit to intelligence tests; and even if an individual is found defective, it is beyond one's powers to force such an individual to enter an institution, if such measure is deemed advisable. I refer to individuals who have not committed a crime, but who, by virtue of being mental defectives, are potential criminals. The only solution of the problem, at present, is possible only after such an individual has been arrested. Then we have legal custody of him and can take measures to prevent him from ever again committing crimes.

What are we to do with such individuals? Let us consider the classification of defectives. As is well known, there are three classes; the idiot, the imbecile, and the moron. Concerning the idiot, it is quite evident that he should receive institutional treatment. I am in favor of keeping such an individual in an institution during his natural life. This is particularly the case where the individual has exhibited a criminal tendency. Such

an individual requires constant watching. He is not responsible for any act he commits and speaking in a medicolegal sense, he is less responsible than the criminal insane, for there are certain instances where a man may be suffering from paranoia or some other form of insanity and yet be fully responsible legally for the crime which he has committed. I will elaborate on this factor in my discussion of the criminal insane.

The imbecile also requires constant observation but not necessarily institutional treatment. If it is possible to improve his condition by either surgical treatment or educational methods, this should be done. If, however, it is impossible to improve his condition in any way, then it is my belief that he should receive institutional treatment indefinitely. Where the condition is the result of glandular defects or disorders of nutrition, steps should be taken to eliminate the cause. Where the defective condition is due to fracture or pressure produced by blood clot, it is our duty to advise surgical treatment and give the individual an opportunity again to approach the normal. It must be admitted, however, that up to the present, the results have not been very encouraging. Adenoid and tonsil cases should be operated upon, and where the teeth show decay, this condition should be corrected. I do not propose to go into great detail, but this much I do wish to impress upon the reader, and that is that certain individuals may be so benefited that they will not require continued institutional treatment, and that it is our duty to aid these people if there is even the slightest possibility of success as a result of treatment. I wish to add that, when an imbecile who has shown a criminal tendency is released from an institution, he should be put on parole for a period of not less than five years. He requires watching.

The moron is the third type of mental defective. There is, in my opinion, more hope for this individual than for the other two, just mentioned. When such an individual is arrested and convicted, he should not be sent to an insane asylum. The place for him is in the intermediary institution. The nearest approach to such institutions are those at Letchworth Village and Rome, N. Y. Such an individual is not benefited by prison. He is too susceptible to suggestion, and for him a prison is a school for crime. He should be taught a trade which will not require mental effort. Teach him to farm, wait on table, to do carpenter work. Let him do the work of a laborer. Don't make a clerk or bookkeeper of him. Teach him to correct his habits. By such correctional treatment you will aid him to correct his criminal tendencies. Study his faults and teach him reading, writing, and simple arithmetic. It is possible to make these individuals useful citizens. The defective is not aggressive enough mentally. It is necessary to stimulate him to greater effort and to encourage him in every way possible.

Taking into consideration the foregoing statements, it may readily be seen that there is great hope of eliminating the defective as a criminal. You can never entirely eliminate him, but you can bring commission of crimes by defectives down to a minimum.

Let us not overlook the fact that many prisoners in our institutions are very shrewd and clever. I refer to those who are not defectives. They very often simulate defectiveness. This is done with a purpose. They know that, if it is certified to that they are defectives and this matter is brought to the court's attention, or to the attention of the Parole Board, they can expect that some consideration will be shown them, either in passing sentence or in their early release on parole. For this reason both Dr. Frank A. McGuire and the author have discarded the Binet-Simon test entirely at the City Prison, Manhattan. Many of these prisoners have been through the test several times and can tell you what your next question will be. There is too much room for simulation when dealing with criminals. I do not propose to discuss the different intelligence tests in this article. Suffice it to state that one must be on his guard against simulation.

From 1 to 2 per cent. of crime is committed by the insane. Much may be accomplished to prevent crime by these individuals. They should, however, be given proper treatment and never be given an opportunity to commit crime. In a great number of such individuals we obtain a history of previous incarceration in insane asylums. The individual has probably been diagnosed as a manic-depressive, precox, or paranoiac. He has "cleared up" somewhat and been allowed to go at large. The next event in his life is usually the commission of a crime. Our insane asylums are so crowded at present that many patients are freed who really should remain in the asylums for a much longer period. It would obviously be unjust permanently to incarcerate the manic-depressive or precox, unless such individuals were in the terminal stage of the disease; but it is an injustice to the public to allow a paranoiac his freedom. This is particularly so in individuals suffering from delusions of persecution. We need look no further than the recent case of the late Dr. Mar-koe. His assassin had been in several insane asylums. His condition was diagnosed as paranoia, and yet he was allowed at large. Then, again, there are the organic insanities. People so afflicted should be permanently incarcerated. They are potential criminals. As concerns manic-depressive, precox, alcoholic psychotics, and other insane persons who apparently "clear up," it is my opinion that such people should be placed on parole for many years after leaving the insane asylum. This is particularly true of the first two, where the patient is subject to remissions. There must be some system of supervision and return to the insane asylum upon the slightest evidence of a remission. In a previous part of this article I stated that a man may be insane and yet not be considered legally insane. This is of importance, for in the insane judgment is usually impaired and the individual may commit an act which is not dominated by a delusion. In such cases I believe that the prisoner should be sent to an insane asylum despite the legal definition of insanity. His brain is diseased and in my opinion he is not as responsible for his act as is a normal individual. We find that an insane person who once commits a criminal act will again com-

mit a criminal act upon remission of his disease. The procedure in our insane asylums is to keep the person until he appears normal again and then return him for disposition by the court. That individual is set at large. When he has a remission, he again commits a crime and is again arrested. The practice of placing such people on parole and having them report at stated periods to a psychiatric clinic is therefore of evident importance in the consideration of the subject now under discussion. Has our policy been correct? Is it to the public interest to release such individuals? There is no doubt that a total release of such individuals or even a release with one year's parole is fraught with danger. Has the individual "cleared up" for good? In 90 per cent. of the cases our answer must be in the negative. Manic-depressive and precox cases are subject to remissions. The periods of intermission vary. In some individuals the period is longer than in others. The general rule, however, is that remissions do occur. If such individuals during these periods are subject to delusions of persecution, they are apt to commit crimes. Furthermore, if they once commit a crime while subject to such delusions, they are most apt to commit a crime upon the return of such delusions. The reason for proper precautions is, therefore, obvious. A person who is suffering from paranoia or from a paranoid trend should never be released. He is a dangerous individual. Suffice it to refer again to the case of the assassination of the late Dr. Markoe.

In the interest of the public, it must be said that our present definition of legal insanity is somewhat to blame for the release of insane persons. If a person knows the nature and quality of the act and knows the difference between right and wrong, he is legally sane. Consider carefully this definition. Then, again, consider also the fact that if a man is suffering from a delusion, and the delusion does not dominate the criminal act, he is legally sane. How does this work out? There is not a paranoiac who commits a crime subject to a delusion of persecution who does not show deliberation and intent and who does not therefore know the nature and quality of his act. In the case of *The People vs. Michael P. Mahoney*, the defendant was accused of shooting the Hon. Wm. H. Polk. He had attempted to kill the late Mayor John P. Mitchell. For weeks this defendant waited for his opportunity. He bought a revolver and bullets. He knew that when he placed the bullets in the revolver and pointed it at the Mayor and pulled the trigger he would injure or kill the Mayor. His intention was to kill. Therefore he knew the nature and quality of his act. He was declared insane solely because his act was dominated by a delusion and because he therefore believed that he was doing right. Our definition of insanity is obviously faulty. We have no adequate method of checking the moral monstrosity. He is checked when it is too late. Our definition does not bring him within the class of legal insane. The definition above quoted precludes such individuals. And yet they are undoubtedly a great menace. Take, for instance, the case of *People vs. Arthur Warren Waite*, the dentist who killed both his father-in-law and

mother-in-law. He was absolutely unmoral. We might term him a moral defective. If we expect to take measures concerning mental defectiveness we should include moral defectiveness. In the class of defectives we must include all sexual perverts. While not strictly insane, such people obviously are potential criminals. It is therefore imperative that measures be taken against such individuals when detected, for the benefit of society and at the same time for the purpose of reducing crime to a minimum.

I have previously made mention of the man suffering from a delusion which does not enter into the commission of the act. I have in mind one case in particular. In this instance the defendant believed that he was a great inventor and benefactor of humanity. He was arrested, accused of stealing a valise in the Grand Central Station. His delusion in no way dominated the act and he was therefore declared sane and sent to prison. If such an individual be undetected by the prison physician he will surely be allowed at large when he has served his sentence, and will be a public menace until he is again arrested. It is, therefore, evident that it should be the duty of commissions in lunacy to interpret broadly the definition of medicolegal insanity.

People suffering from organic insanity should be incarcerated for life. There is no hope that such individuals will recover.

From the foregoing it may therefore be said that disturbances in the function of the cerebrospinal system, as well as maldevelopment of that system, are important factors to be considered in discussing the causation of crime. It is the writer's opinion that much remains to be done in the practical application of this knowledge. Institutions should be established where both the mental and moral defective may be cared for. Remove this cause and you will have taken a great stride in the direction of public protection. In this respect much remains to be done by the medical fraternity. The physician and specialist owes as much a duty toward the public as does any ordinary citizen. As physicians we should aid in the maintenance of order. Let us therefore work together toward a common purpose and that is, to dispose adequately of the insane and mental and moral defectives in the proper institutions so as to eliminate them as a cause of crime.

Let us now consider the offender whose criminal tendencies may be attributed to environment, opportunity, and temptation, or heredity. We know that environment is a potent cause of crime. Due to improper home training the youth begins by "hanging out" on the corner with others. A social club is organized. "Crap shooting" and card playing as well as horse-race betting are the pastimes of the "social club." The next "hangout" of the gangster is the pool room. Here he meets criminals of all descriptions. Here he may learn to take drugs. Decent English in such places holds one up to ridicule and brands the youth as a "sissy." The next step is the cabaret. Here the youth hears suggestive songs; learns to dance passion-producing dances; sees the girls dressed in a way which might more appropriately be termed undressed; meets these girls and indulges

in sexual excesses, and finally winds up with some venereal disease. Very few of these individuals are adept at their every day business. The victim needs money in order to meet his "social" obligations. He needs money with which to pay his debts. Thus we see produced an excellent foundation for crime. The description just given is by no means a day dream. It is an exact description of the life history of the majority of offenders, particularly the habitual offenders. Who is to blame? First, the parents, and secondly, society. Parents are to blame for their laxity. Without doubt a girl requires closer watching than does a boy. Parents know this and oft are led astray by a misinterpretation of this fact. They believe that a boy requires no watching and that he can take care of himself. If he contracts a venereal disease and the father discovers it, he often overlooks the fact, or makes light of it, because in his youth he probably had contracted a similar disease and he believes in the saying so often heard, "You're not a citizen until you have had it." The young man requires strict watching these days. The rule should be laid down to him, requiring him to live up to certain moral standards. I do not wish to convey the thought to the reader that every boy who "hangs out" on street corners becomes a "crook." This is not so. The mere fact that a young man makes a practice of standing on the corner with others does not make him a thief. It is the laxity of home discipline and the following up of gang life that leads to crime.

How is society responsible? By permitting the lax moral atmosphere which now exists. More attention should be paid to the development of a moral sense in the child at school. The school should be the place not alone for mental development, but also for moral development. High school instructors and principals should place a ban upon silk stockings, low neck, transparent blouses, short dresses, and powder and paint among their students. This would be a good beginning. To verify my statement the reader need but visit any one of our high schools for girls.

Society should discourage daughters and sons from visiting cabarets. Society should boycott these places. Society should boycott all suggestive songs and dances. I know from reliable sources that it is practically impossible to have a song published through certain well known publishers which is not in some way suggestive. Compare some of our present day song "hits" with those of twenty years ago. It is impossible for the police to do anything toward remedying such conditions unless there is active cooperation from the public. I do not advocate puritanism. I do advocate a marked correction of present day social conditions.

This little discourse is probably not in strict line with medicine. It, however, deals with the moral sense and is therefore appropriate.

Concerning opportunity and temptation there is not much to be said. I have seen many young men in prison arrested for forgery or grand larceny whose downfall was due to these causes. The usual history is that the individual has been "playing the races" and lost heavily or else was "tipped off" on an opportunity to "clean up" in

the stock market and the "tip" proved false, or else has gotten into debt some other way. He is a bank clerk or he is employed where he has access to large sums of money. He usually comes from a good family. He had the opportunity to take money and he could not resist the temptation. This is a cause of crime which will never be eliminated. It dates back to the days of Adam and Eve, and serves to illustrate the weakness of human nature.

Let us also consider under this heading certain conditions which at present exist and are directly responsible for criminal acts. First and foremost is the deplorable condition of our subways, elevated railways, and street cars due to overcrowding. Think of our daughters placed at the mercy of degenerates. One need but enter the subway stations at Fourteenth or Forty-second streets any evening between the hours of 5 and 6. The burly subway guard keeps shoving men and women into the train caring little for the comfort of the people. Old and young, male and female, are shoved into the suffocating, already overcrowded trains and stand huddled together. What better field can be imagined for the degenerate and pick-pocket? Directly before you you may find an individual who breathes into your face. Now and then somebody coughs and another sneezes. What a fertile field for the communication of disease! Women who may be fortunate enough to occupy a seat are placed at the mercy of men standing. The latter in many instances delight in pressing their knees against those of the women and gain sexual excitation or satisfaction from the contact. Certainly something should be done to remedy this deplorable condition.

Next let us consider the moving pictures. In my opinion the great majority of pictures now exhibited are entirely moral and indeed of benefit to the people. There are, however, some pictures which should be suppressed. All suggestive scenes should be censored. Pictures dealing with sex education, while instructive, should, nevertheless, be limited in exhibition to those ranging in age from seventeen upward. Wild west pictures should be prohibited. They influence the youth and stimulate criminal tendencies.

Under the heading of opportunity and temptation we may properly consider unemployment and the soldier problem as a cause for the commission of crime. These two factors are closely associated. Unemployment is a direct reaction to prosperity which existed during the war. Such conditions exist following all wars. It is unnecessary to go into detail. We have not done our duty toward the soldier. While the war lasted he was a hero and nothing was too good for him. At present he is an outcast. He has been discharged from the army as physically fit, after having spent months on the firing line. He has been gassed and shell-shocked and as a result is left with a nervous system which is anything but evenly balanced. He has done his duty. Have we done ours? Emphatically no. Let the reader visit the prisons where these men are awaiting trial. In one cell you come upon a soldier who has his cell light shaded and who sits huddled in one corner. He is afraid. Afraid of what? He cannot tell you.

Pale and emaciated, eyes sunken, he is what remains of one whom the people worshipped as a hero. While one is speaking to him he suddenly falters, drops on his cot, the perspiration rolls from his skin, and his pulse becomes feeble and very rapid. What is the end? Ward's Island. You pass along, shake your head. Another case of shell shock. This boy was arrested for receiving stolen goods. His friends recognized in him a weak-minded individual and used him as their tool.

The next case is a prisoner who complains constantly of headaches and dizzy spells. He was gassed and shell-shocked. While walking along the street he would suddenly become lost and wander and when he came to would find himself in another place than his original destination. This man is accused of committing a crime which he does not remember. He tried to obtain a position but found it impossible to work indoors. He tried outside work. Everything went smoothly until the weather changed, when he would become "choked up," would feel as if he were smothering, cough incessantly, and on several occasions had hemorrhages. He became desperate. He committed a crime, the details of which he cannot remember.

These are not fantastic creations of the mind. They occur every day. In time of war we as a unit are willing to sacrifice everything for our country. To prevent the commission of crime by soldiers let the government do something for these unfortunates. I do not wish to convey the idea that every soldier who commits crime is in a way irresponsible. There is no doubt, however, that the great majority of those who have been gassed or shell-shocked are unstable.

Finally there is heredity as a cause of crime. There is a celebrated case of grandparents who had a pawnshop and were arrested for receiving stolen goods. Their children inherited a criminal tendency and several of them served terms in jail, and their children, too, in turn inherited the tendency, one son and one daughter being at various times arrested for larceny. Usually there is obtained a history of parents who were addicted to liquor. The father had served time in jail so often that it was looked upon as commonplace in the family and the children growing up in such environment took to crime as a natural sequence. Very little can be accomplished toward eliminating such individuals as causative factors. The suggestion at once arises that such people should not have children. There is, however, no means of controlling the situation.

In conclusion I wish to state that it is my belief that crime can be reduced to a minimum if we seek the cause and eliminate that. We shall never see the time when jails will be unnecessary.

Eliminate the cause and you have done everything possible to bring about the ideal situation.

958 EAST 156TH STREET.

Cosmetic Nasal Surgery.—Esthetic plastic surgery of the nose is apparently extending over the world as a specialty. Dr. J. Bourguet publishes an illustrated article on the subject in the *Revista de Medicina y Cirugía* of Havana. The late Dr. John O. Roe is given credit as the originator of esthetic nasal surgery.

CONGENITAL HYPERTROPHIC PYLORIC STENOSIS IN INFANTS.

By P. I. NIXON, M.D.,
SAN ANTONIO, TEXAS.

CONGENITAL hypertrophic pyloric stenosis is a condition occurring in infancy, characterized by an enormous hypertrophy of the pyloric sphincter which, in turn, leads to pyloric obstruction with its attendant symptoms. The names of four men are preeminently associated with this disease: Downes,¹ Strauss,² Bevan,³ and Dean Lewis.⁴

Etiology.—The etiology is quite speculative. The evidence seems to point to some disturbance of the sympathetic nervous system, causing overaction of the muscle and consequent hypertrophy. It is not known whether the hypertrophy begins before birth in every case, although one case of pyloric tumor in a seven months fetus has been reported. Strauss,² at operation, has noticed rhythmic contractions of the pylorus, and he believes that these give rise to the hypertrophy. He calls attention to the fact that the tumor is always proportionate in size to the age of the patient; that is to say, the younger the patient, the smaller the tumor, and vice versa.

Thomson of Edinburgh, writing in one of the Osler Memorial Volumes,⁵ advances the belief that the hypertrophy is due to an incoordinated overaction of the sphincter. His explanation is as follows:

It is known that the normal foetus swallows a considerable quantity of amniotic fluid during intra-uterine life; and, as this implies a certain amount of co-ordinated muscular action of the stomach and pylorus, it is believed that the supposed in-co-ordination between these parts begins when the fluid first passes through them. There is reason to believe, however, that the muscular action may not at this period be vigorous or continuous, and that therefore, by the time the child is born, only a small degree of hypertrophy will have occurred. After birth, when regular feeding has begun, the force of the muscular action and the in-co-ordination will tend to increase so that the hypertrophy will progress much more rapidly than during intra-uterine life. It is in accordance with medical, surgical and pathological experience that the pyloric tumor does grow larger and harder while the active symptoms continue. This is just what might be expected, for, as John Hunter pointed out long ago, a tendency to hypertrophy as the result of repeated forcible contractions is a property of all muscles and is greater in involuntary than in voluntary muscles. It is also extremely probable that tissue-growth of this sort is specially active in early infancy.

As to the frequency of the condition, Hill⁶ states that it occurs once in every 200 babies.

Symptoms.—In most cases symptoms do not appear earlier than ten days or two weeks, the child gaining in weight quite normally, nothing out of the usual being noticed up to this time. The majority of cases begin between the second and fourth weeks, although the onset may be as late as the sixth or eighth week. The onset, as a rule, is quite sudden. Without any apparent cause, the child begins to vomit and no relief is to be had. The vomiting is projectile in type, persistent, and not amenable to the usual therapeutic measures. The child is likely to be very hungry and satisfying its hunger tends to accentuate the distressing vomiting. Vomiting may follow each nursing or the stomach may be emptied at alternate periods. Vomiting of small quantities of ingested food is

the exception; the rule is to expect large quantities, forcefully projected from the mouth. The vomitus consists of food taken, plus the secretions from the stomach; bile is not to be expected. Persistent, projectile, unyielding vomiting, then, is the most important symptom, which, in itself, should suggest a possible diagnosis of hypertrophic pyloric stenosis.

In addition to vomiting there should be mentioned tumor, peristaltic waves, gastric retention, constipation, loss of weight and emaciation. Downes considers the presence of a pyloric tumor pathognomonic of the disease. He states that it is present and palpable in practically every case. Strauss, on the contrary, believes that palpation of the tumor is a matter of the personal equation, adding that it is a symptom of negligible value in comparison with his method of radiographic examination. The tumor, when present, is felt to the right and above the umbilicus as a freely movable nodule about the size of a small olive. It is best palpated when the stomach is empty.

Visible peristaltic waves are in evidence as the result of an attempt on the part of the stomach to overcome the pyloric obstruction. Their presence is a constant phenomenon. They are best elicited after the child has taken food, when they appear as rhythmic waves passing across the abdomen from right to left and slightly downward. The amount of gastric retention varies with the degree of obstruction and the frequency of vomiting. Retention of food for three or more hours is not unusual.

Constipation follows as a result of the absence of food and fluids in the intestines. In a typical case the stools show no evidence of the presence of milk. They are scant in amount, green in color from the excess of bile and not dissimilar in appearance to meconium. Loss of weight develops rapidly from food and fluid starvation. In cases of long standing extreme emaciation may be present, the child having wasted away to a mere skeleton.

Diagnosis.—In a majority of cases a diagnosis can be made from the symptoms just mentioned. There is one diagnostic means about the value of which Strauss⁶ is very enthusiastic, and that is the fluoroscope. He describes the method as follows:

A small amount of bismuth is added to mother's milk and the child is placed under a horizontal fluoroscope. It is allowed to nurse from the bottle while we watch the passage of the bismuth milk through the esophagus into the stomach. If the child is permitted to lie flat on its back, the bismuth milk gathers on the left side of the vertebrae as a large, round mass and will lie there indefinitely. If the baby is rotated toward the right side, almost on its abdomen, we will see the bismuth gradually gravitate toward the pyloric end of the stomach, and one notices immediate peristaltic waves in the pyloric antrum and pylorus. A small amount of bismuth is now squirted through, and then the pylorus clamps down tightly. Immediately peculiar and characteristic, snake-like, rhythmic, peristaltic contractions can be seen in the pylorus which are independent of the rest of the stomach. This is absolutely pathognomonic of this condition. The fluoroscopic examination consumes only about two or three minutes at this time. At the end of two hours the examination is repeated to see if anything has passed through, but as a rule the same picture is observed. At the end of four hours the child is again examined for the last time. At the two latter examinations roentgenograms are taken.

Strauss is of the opinion that this method is useful also in differentiating the medical cases from

those that should be treated surgically; he believes that in a given case surgical interference is indicated if one half or more of the bismuth-milk remains in the stomach as long as four hours.

Aside from the very occasional case in which there is obstruction at or near the pylorus from some extra-gastric cause, only one condition simulates that under discussion, namely, pylorospasm. In pylorospasm, the symptoms are not likely to be so severe or so persistent. In making the distinction Haas⁷ advocates the use of atropin in 1/1000 grain doses by mouth every three or four hours till symptoms of physiological saturation appear. Since atropin paralyzes the vagus endings, it tends to relieve pylorospasm.

Treatment.—An impression gained from a limited clinical experience and from a survey of the literature of this subject, leads me to believe that this is practically always a surgical condition; at any rate this is true in cases that are at all severe. However, the usual teaching is to institute medical measures (gastric lavage, careful feeding, etc.) first in the hope of obviating the necessity of surgical intervention. It has been estimated that less than one-third of the patients recover under medical treatment; unless the fluoroscope can make the distinction, there is no way of even predicting which medical case will eventually become surgical and which will not. Should operation become necessary, valuable time will have been lost and the patient will have depreciated as a surgical risk.

Two operations are to be considered: the Fredet-Rammstedt pyloroplasty, and Strauss' modification thereof. The mortality from gastroenterostomy is so high that it has been superseded by the simpler pyloroplasty. Most surgeons advocate the Fredet-Rammstedt operation, its simplicity being its greater recommendation. On the other hand, no one can produce statistics at all comparable to those of Strauss, who had a mortality of less than 3 per cent. in 103 cases. Downes⁸ had a mortality of 17.1 per cent. in 145 cases.

The Fredet-Rammstedt operation is performed as follows: The abdomen is opened in the usual manner through a two-inch incision above and to the right of the umbilicus. The greater curvature of the stomach is grasped and the pylorus is exposed. The pylorus is drawn outside the abdomen and the thickened muscle grasped between the thumb and the index finger of the left hand. Choosing the most avascular area, an incision is made through the peritoneum and partially through the sphincter, beginning on the stomach side. As the duodenum is approached great care should be exercised, as the muscle is less hypertrophied at this point and the mucosa more delicate. This can not be made too emphatic, because the duodenum has been opened many times at this step of the operation; and while this accident need not be serious, it adds an element of uncertainty that is immeasurable. Should the mucosa be wounded, it is immediately sutured. A pair of closed artery forceps is then introduced between the cut edges of the muscle and gently opened. This procedure is repeated all along the incision until the entire muscle is separated and the white submucosa is visible beneath. The raw surface may or may not be covered by omentum. This ordinarily completes the operation.

However, it would seem well to embody a further step toward increasing the lumen of the pylorus after the method of Strauss; this can be done by shelling the mucosa from the muscle, using a blunt dissector. The wound is then closed in layers, great care being used in obtaining an accurate and secure closure. Bevan is particularly emphatic on this point. Wound repair in these patients is slow and opening up of the wound is not an uncommon accident. An extra safeguard is to be found in applying a firm adhesive dressing entirely around the child's abdomen.

Just a word about Strauss' operation. After the muscle has been divided, the division being made for the most part by a scalpel handle, Strauss shells out the mucosa widely. He then splits the inner part of the muscle on each side, turns the flaps forward and sutures them in front of the tube of exposed mucosa. The free end of omentum is then sutured over the raw surface.

Most authorities are of the opinion that the Fredet-Rammstedt operation has the appeal of "complete efficiency and absolute simplicity," and that modifications are unnecessary.

Ether is the anesthetic of choice, although Bevan is a strong advocate of local anesthesia.

Post-operative Management.—Particular attention should be given to keeping the child warm during the operation and after its return from the operating room. If conditions necessitate it, hypodermoclysis of about 100 c.c. of normal saline solution may be used, or a transfusion of blood may be given, using the median basilic vein or the longitudinal sinus. An ounce of soda and glucose solution is given by rectum and repeated every 3 hours; this accomplishes two things: it supplies much needed fluid and combats acidosis, which is so prone to develop in these half-starved babies. As soon as consciousness has been regained, water and breast milk are given alternately in teaspoonful doses every two hours. The amount is gradually increased till at the end of 24 hours, half an ounce is taken at each feeding. At the end of a week the baby should be taking two ounces of milk every 3 hours. No harm can come of putting the baby to the breast after four or five days. A teaspoonful of castor oil is given on the second day. Gastric lavage may be resorted to if there is excessive accumulation of gas or too frequent vomiting.

Anatomic confirmation of the value of the Fredet-Rammstedt operation is found in a case reported by Ransahoff and Woolley.¹⁰ This patient died, seven months after operation, from the effects of an enlarged thymus. At autopsy it was found that the defect between the cut ends of the muscle had been filled in with fibrous tissue in such a way as to preserve the sphincter action. There was no evidence of diverticulum formation or hernia at the site of the scar. It is interesting to note that the hypertrophy of the muscle had disappeared.

My experience with this condition is limited to two cases. Both presented typically the symptoms enumerated above, so that their review would be of no special interest. Both were operated on by the Fredet-Rammstedt method. The first patient developed symptoms on the twenty-fifth day and was operated on the twenty-seventh. He is now three years old and has never had any trouble referable

to the gastrointestinal tract. The second patient was operated on in the third week and made a satisfactory recovery, but died, after leaving the hospital, from an intercurrent intestinal infection.

Summary.—1. Hypertrophic pyloric stenosis should be suspected in any infant who develops persistent vomiting, gastric peristaltic waves, pyloric tumor, non-fecal stools, loss of weight and other minor symptoms.

2. This condition is probably always surgical.

3. The Fredet-Rammstedt operation makes the appeal of complete efficiency and absolute simplicity.

THE RELATION OF ECTOPIC PREGNANCY TO CHRONIC ENDOCERVICITIS.*

BY M. O. MAGID, M.D.,

NEW YORK.

WHILE much has been written on the subject of ectopic pregnancy, the literature records only the end results of this pathological process, without giving a logical explanation as to its antecedent stages. All observers are agreed that a diseased tube is an essential factor in the production of this affection.

It is the object of my paper to call attention to a condition which is nearly always present in those patients suffering from ectopic pregnancy, and is fundamentally the cause in nearly every case. I refer to chronic endocervicitis, the timely and proper treatment of which disease will greatly reduce the possibility of ectopic pregnancy, and may thus be considered to stand in the relation of a prophylactic measure.

Extrauterine pregnancy was described in the eleventh century by Albucasis, an Arabian, after which time the subject was referred to at various periods, as the different types of this anomaly in pregnancy were discovered. It was about the middle of the last century when the true interpretation of what was then diagnosed as pelvic hematocoele or pelvic hematomata, was gradually evolved.

In the great amount of literature elucidating this condition, the subject of underlying factors, and the course of pathological events, is conspicuous by its insufficient and contradictory deductions. Thus Lawson Tait, Tilt, and others recognized that these patients suffer from chronic salpingitis, claiming that the destruction of the tubal epithelium, with loss of ciliary action, impedes the passages of the fertilized ovum into the uterine cavity. J. W.

*Read before the Bronx County Medical Society, November 17, 1920.

Williams, on the other hand, demonstrated active cilia in all his cases of ectopic pregnancy. J. Zedel corroborated the findings of Williams, showing the cilia in motion in several recent specimens. Vautrin suggested that the implantation of the ovum in the tube was dependent upon an overdevelopment of the lutein cells, with resulting excess of the internal secretion, and not upon any disease of the tubes or uterus. O. V. Huffman advanced the hypothesis that ectopic pregnancy is determined by an anomalous imbedding area, which has been misplaced during the development of the tubes and uterus. Howard Kelly states that the simplest idea in the etiology is that the absence of cilia retards the progress of the ovum toward the uterus. He attaches far greater importance, however, to the fact that he finds in his experience many cases where tubes are bound down in the pelvis or crossed by fibrous bands, with the fimbriated extremities glued down to the ovary so as to be incapable of receiving the ovum except from a very limited area. He maintains that such adhesions may readily cause an obstruction or an ileus of the tube and thus prevent the downward progress of the ovum. Besides the inflammatory condition that may bring about unnatural fertilization, J. M. Keyes speaks of mechanical factors, as uterine myomata, diverticula and kinks which offer obstruction to the ovum and prevent its entrance to the uterine cavity.

It thus appears that whatever difference of interpretation and observations are noted, all observers agree upon the invariable existence of one pathological manifestation, namely, tubal distortion as the result of adventitious bands or adhesions.

Omitting in the present consideration the very rare instances of ectopic pregnancy in congenital diverticula of the tube, it is a significant fact that while every case presents the evidence of peritubal inflammation productive of adhesions, the tubal lining is invariably found normal. The presence of normal cilia would substantiate this latter statement, and the question naturally arises, what is the cause, course, and nature of the peritubal adhesions, productive of the distortions, which favor the nidation of the fertilized ovum in the tubal wall?

It is a well established fact that under normal conditions, every fertilization of the human ovum occurs regularly within the lumen of the tube, from which locality it is impelled by tubal peristalsis and ciliary action, into the uterine cavity. From this established fact it would follow as a natural corollary that any inhibition of the normal peristalsis of ciliary mobility, would arrest the ovula migration and result in the tubal nidation of the fertilized ovum. And the question which presents itself is—whence and by what route does this insidious infection, resulting in such tubal distortion, travel? The question becomes clinically significant when it is recalled that a very large proportion of women, afflicted with ectopic gestation, give no history of a previous infection.

In his studies on chronic endocervicitis, Sturmdorf states the following: "The course of chronic endocervicitis is insidious and its symptoms vary with a wide range, depending on the intensity and progress of the infection. Mild cases, limited

to the superficial layers of the cervical mucosa, will present a leucorrhea as the only symptom, not necessarily copious or purulent, but intractable. In the progressive cases, the ascending lymphangitis envelops the perimysial sheaths throughout the uterine musculature and splints and immobilizes the elementary muscle bundles by plastic infiltration of their sheaths. Ramifying the entire myometrium along these sheaths, this chronic lymphangitis then converges to the lines of the main lymphatic channels. Its course is evidenced by paracervical exudates and velamentous bands or meshes which kink and agglutinate the adnexa, inhibit tubal peristalsis, create diverticula, that establish ectopic *possibilities*, or occluding the tubal ostia, insure sterility."

Here we find the pathological course of endocervical infection leading to the operative findings so uniformly described by all observers. Furthermore, the clinical course of chronic endocervicitis, as thus depicted in its insidious progress, explains the symptomless interval presented by both nulliparous and multiparous patients, who in the course of time may develop extrauterine pregnancy; for, as Sturmdorf says, "a chronic endocervicitis may date its origin from an infantile vulvitis, which invariably means an endocervicitis; or from mildly infected puerperal traumata in multipara."

Chronic endocervicitis thus stands exposed as the fundamental causative factor in the majority of ectopic pregnancies. While such a relation of cause and effect may appear extravagant to those who are still adhering to older doctrines, the most superficial investigation of their cases along these newer lines of pathological reasoning, will supply ample proofs of the correctness of this theory.

A few cases from among many will substantiate this contention:

CASE I.—S. W., age 32 years, September 19, 1914. Complaint—Bleeding for twenty-four hours, fainting spells, severe pain in right lower quadrant of abdomen; vomiting. Patient pale and looking extremely ill. Physical examination shows bleeding from vagina, no clots; abdomen very tender; cervix lacerated, soft; uterus enlargement to slight degree and soft; limited mobility. Right adnexa, palpable, enlarged, and very tender; left adnexa, some tenderness in fornix.

With a history of irregular bleeding, after having been two weeks overdue, together with physical examination, I concluded that I was dealing with a ruptured ectopic. I sent the patient to the Polyclinic Hospital, where, on laparotomy, we found a ruptured right ectopic pregnancy. After recovery, she gave a history of having suffered from a leucorrheal discharge since her first pregnancy, six years ago; that three and a half years after, she again became pregnant and had been aborted, with resulting sepsis; she then went to Mt. Sinai Hospital, where she was treated for four weeks.

After the patient left the Polyclinic Hospital her leucorrheal discharge continued; she had irregular menstruation with constant backache. I treated her palliatively until November 13, 1917, when she consented to a tracheloplastic operation, which was performed at the Community Hospital. She was discharged after five days, November 18, 1917. Since that time the patient has had no discharge, no backache; her menstruation has become regular and of moderate flow. The last time I saw this patient was in October, 1920.

Summing up this case, we have every evidence of the existence of chronic endocervicitis prior to the ectopic.

CASE II.—B. K., age 30 years, December 16, 1916. Complaint: Pain in lower abdomen, excessive menstruation, leucorrhea, constipation, nausea. Menstruation

began at 12½ years. Regular, every 28 days for 5 to 6 days, moderate flow, no pain. Married at 23 years; two children, six years and three years; confinements normal; no miscarriages; menstruation in last two years regular as before; last menstruation November 14, 1916.

Physical examination: Abdomen, tenderness in right lower quadrant. Vaginal, cervix lacerated and infected. Uterus, normal size and position, limited mobility. Right adnexa, thickening in fornix and tender on pressure. Left adnexa, not palpable.

Recommended a tracheloplastic operation, which was refused. Applied local treatment for several weeks, with some improvement of complaint.

November 1, 1917, was called to her home in emergency. A brief history and examination convinced me that she was suffering from ruptured ectopic. I sent her at once to nearest hospital (Lincoln). On laparotomy, a ruptured right ectopic was found. She made an uneventful recovery.

January 6, 1918, patient called at my office because of weakness, backache, leucorrhea; menstruation was regular, but profuse. I applied local treatment and again advised a tracheloplastic operation in order to save the other tube. This was refused. On May 17, 1918, however, I performed the operation at the Community Hospital. Patient left the hospital on the fifth day in good condition.

April 24, 1920, patient complained of pain on right side for two days prior to menstruation, for the last two months; no leucorrheal discharge; menstruation normal in amount, regular in time. Physical examination showed uterus freely movable, no thickening in fornices; slight tenderness on right side; left side normal.

The slight premenstrual pain is no doubt due to congestion. This case complained of symptoms and showed evidences of chronic endocervicitis nearly one year prior to her ectopic pregnancy.

CASE III.—E. M., 32 years, January 31, 1917. Complaint: Irregular bleeding, backache, nervous. Menstruation began at 13 years; comes every 28 days; 4-5 day type; little pain; moderate amount. Married at 23 years; two children, 8 and 4 years old; no miscarriages; menstruation continued to be regular until last confinement; last menstruation, December 15, 1916. Physical examination showed patient had exophthalmic goiter. Gynecological examination: Lacerated perineum; cystocele; rectocele. Cervix lacerated and infected (chronic endocervicitis). Adnexa thickened and tender.

Owing to the exophthalmic goiter, gynecological intervention was deferred. I gave local palliative treatment with some relief.

May 3, 1918, patient called, complaining of bleeding and severe pain on right side of abdomen. Menstrual function had been irregular for several months. Last menstruation came on time, lasting four days; patient was clean for a week, when bleeding recurred, with severe pain on right side.

Gynecological examination showed noncoagulable blood at vulva; cervix lacerated and soft; uterus, slight enlargement, limited mobility; adnexa, right side, small mass, very tender; left side, some thickening, but not palpable.

Diagnosis: Ectopic pregnancy. Patient ordered to bed; gave her codiene for the pain. She stayed in bed until May 22, 1918, bleeding continuing during all this period. Advised operation. A laparotomy on May 23 revealed right ectopic, small cyst of the ovary and chronic appendicitis. Patient left the hospital June 6, 1918, in good condition. Since operation, patient reports disappearance of goiter and general improvement.

CASE IV.—J. S., age 24 years, August 4, 1920. Complaint: Sterility, continued bleeding for past five weeks, pain on right side for three weeks; general weakness. Menstrual history: Menstruation began at 15 years; irregular, covering 5-6-7 weeks, lasting 4-5 days; moderate amount; not painful. Married four years ago; never pregnant; always had leucorrheal discharge since marriage. Present trouble dates back five weeks. Her menses had been delayed two weeks. Bled for a few days and became clean. Began to bleed again and kept up either bleeding or staining for past five weeks; three weeks ago developed pain on right side.

Physical examination showed bleeding at vulva, noncoagulable blood. Perineum normal; cervix, soft; os, patulous; uterus, anterior, not appreciably enlarged; on attempted manipulation experienced pain and soreness on right side. Adnexa, left side, not palpable; right side, distinct enlargement and thickening of tube, tender to touch. When blood was wiped away from cervix a distinct reddened zone around the os could be noticed.

Diagnosis: Ectopic pregnancy, accompanying chronic endocervicitis. Ordered to bed for a few days.

September 7, 1920, saw the patient again, when all her symptoms were aggravated. Owing to the patient's refusal, the operation was not performed until September 17, 1920, when a right ectopic was removed. Patient left the hospital October 2, 1920, in good condition.

In closing, I would emphasize the essential phases in the etiology of tubal gestation in the following summary:

1. Fertilization of the ovum occurs normally in the tubal lumen.
2. Tubal nidation of the fertilized ovum results from an arrest of the fertilized ovum in its normal progress toward the uterine cavity.
3. The only essential factor productive of such an arrest or impediment to the normal transit of the fertilized ovum is the presence of tubal diverticuli or sacculations.
4. Tubal diverticuli and sacculations may be congenital or acquired.
5. The congenital variety is extremely rare, while the acquired form is extremely common.
6. The most prolific and constant cause of the acquired form, hitherto obscure in its etiology and course, stands revealed by Sturmdorf's investigations, as an insidious perisalpingitis, invariably resulting from chronic endocervicitis.
7. Chronic endocervicitis, with its resultant perisalpingitis, thus stands in the direct relation of cause and effect in the production of tubal gestation, and it follows as a logical deduction, that the eradication of chronic endocervicitis presents a prophylactic measure in tubal pregnancy.

Pneumonia.—William Henry Porter emphasizes the importance of elimination in cases of pneumonia. When it is impracticable to keep the bowels active by the use of laxative agents, high rectal irrigation, using large quantities of plain water, will often be the means of saving a pneumonia patient. Active elimination must be maintained at all hazards. Without it the patient will almost inevitably die.—*Western Medical Times*.

THE RELATION OF THE PERSISTENT THYMUS GLAND TO CRIMINOLOGY.

By S. J. MORRIS, M.D.,

MORGANTOWN, W. VA.

PROFESSOR OF ANATOMY, WEST VIRGINIA UNIVERSITY MEDICAL SCHOOL.

DISTURBANCES of the mind may be divided into three types: (1) The type which in the development of the brain there is a deficient number of cells in the whole or part of the brain; (2) the type which includes those individuals who during life have received an injury which involved the brain substance; (3) the type which includes those individuals in which there is in the brain a normal number of cells but the change is in the tissues from which these cells receive their potential energy and nutrition.

When a cell responds to an outside stimulus and performs an act the process is called the functional activity of the cell. The point at which this outside stimulus causes the potential energy stored up in the cell to be changed into kinetic energy and to give off an outgoing impulse is spoken of as the threshold of functional activity. If the chemical composition of the surrounding tissues is normal the threshold is normal. If it is altered then the threshold may be either raised or lowered. The normal threshold is more or less at a constant level. If this level is raised then it requires a greater stimulus to cause the cells to react. If it is lowered then the cells respond to impulses which ordinarily would produce no impression.

The emotions, especially love, hate, and fear, are kept within the realm of sanity by inhibitory impulses coming from the intellectual side of the brain. If the threshold is normal there results an emotion which conforms to what we consider rationality. But if through a chemical change in the brain tissue the threshold of cell groups in the emotional part of the brain has been altered it will be impossible for the inhibitory impulses from the intellectual side of the brain to influence the emotions, and therefore there will result an action which is purely impulsive, which lacks the mental attributes of judgment of right or wrong or thought of consequences.

One of the chief causes of disturbances of the threshold can be attributed to the ductless glands. It is a well known fact that in persons in whom the thyroid substance is increased, explosive reactions occur from incoming impulses which ordinarily would hardly produce an action. The converse is also true, that when the thyroid substance is deficient the person will not respond to an incoming impulse which normally would have caused a response. What is true of the thyroid is also thought to be true of the other ductless glands.

Anatomy of the Thymus.—The thymus is a ductless gland situated in the anterior mediastinum and in the neck, reaching from a level of the fourth costal cartilage upward on the trachea as high as the lower border of the thyroid. If found when its growth is most active, it will be seen to

consist of two lateral lobes placed closely together along the middle line. Below it rests on the pericardium and is separated from the aorta and the great vessels by a layer of fascia. It is about two inches in length, an inch and a half in breadth and an inch and a quarter in thickness. It is of a reddish gray color which changes to a white or yellow as the gland undergoes involution. This involution takes place by a fatty infiltration that leaves an exact model of the gland in fat. The gland is covered by a fibrous capsule which sends numerous septa into the gland substance dividing it into lobules which in turn divide into follicles. Each follicle consists of a cortex composed mainly of lymphoid cells, reticular tissue, a network of finely branched cells, and a centrally located medulla composed of a few lymphoid cells scattered among which, especially toward the center, are granular cells and concentric corpuscles. The concentric corpuscles are composed of a central mass of one or more granular cells and a capsule of epithelioid cells which are continuous with the branched cells of the cortex. The arteries are derived from the internal mammary and the superior and inferior thyroid arteries. The nerves are derived from the vagus and the sympathetics.

At birth, the thymus weighs from fifteen to twenty-eight grams. After the second year it does not grow in proportion to the other organs of the body, and gradually loses its thymic structure and becomes adipose in character, until at puberty it is very small. In some cases it may persist even until old age. It is with this type that I have come in contact.

Laboratory Findings.—In the anatomical laboratory of the West Virginia University Medical School work has been done on about 192 bodies sent in by the different public institutions of the State. Of these 52 came from the insane hospitals, 10 came from the tuberculosis sanatorium, 74 came from the poorhouses, 20 came from the State penitentiary, and 36 came from undertakers over the State. The age of these bodies ran from seven-teen up to eighty-six years. They were all males but ten. In this number I found twenty-two persistent thymus glands. Twenty of these glands were taken from the bodies of criminals sent in by the State penitentiary. All of these were first or second degree murderers with the exception of one, who was a rapist. Seventeen were first degree murderers and hanged in the State penitentiary and three died following a prolonged illness. Of the other two, one came from the insane hospital and the other from a poorhouse. The one from the poorhouse was 22 years old and had a thymus gland that weighed five grams. Histologically, it showed very little thymus tissue left in the gland. These glands ran in weight from five grams to twenty-nine grams. The ages of the persons were from 22 to 56 years, and all were males. The largest gland measured 5½ in. long, 1 in. wide, and 1 in. thick, while the smallest was 2 in. long, 1 in. wide, and ½ in. thick. Histologically, they showed just the normal thymic structure.

Conclusion.—The conduct of a person seems to

be the result of all his impulses and inhibitions, the impulses causing him to act and the inhibitions causing him to stop and consider his actions. We, therefore, have two kinds of action; one in which the impulses predominate, which is an impulsive action, and another in which the inhibitions predominate, which results in a premeditated action.

If through a change in the chemical composition of the surrounding tissues there is a trophic disturbance of the brain cells there results an abnormal response to a stimulus, hence there is not the proper relationship between the impulses and the inhibitions.

It has been shown that an abnormal secretion of the thyroid gland, causing a trophic disturbance, interferes with the relationship between the impulses and the inhibition so that a person responds to emotions that he would not respond to normally.

It has also been shown that out of 20 criminals dissected all had persistent thymus glands.

From this I feel that I am justified in drawing the conclusion that the persistent thymus is in some way accountable for the mental state that caused these men to be criminals.

CONGENITAL ELEVATION OF THE SCAPULA:

WITH REPORT OF A CASE.

By JACOB GROSSMAN, M.D.

NEW YORK.

CHIEF OF THE ORTHOPEDIC CLINIC, LEBANON HOSPITAL; CHIEF OF THE ORTHOPEDIC CLINIC, STUYVESANT POLYCLINIC; INSTRUCTOR OF ORTHOPEDICS, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THIS deformity was first described by McBurney and Sands and was communicated to the German literature by Sprengel in 1891. The condition may be unilateral or bilateral. It is more commonly the former. It is a somewhat unusual congenital deformity, in which one scapula is raised in its relation to the thorax and the clavicle and also to the opposite scapula. The scapula is not only raised, but generally is so rotated that its upper angle approaches the spine. Scoliosis exists in connection with it in the majority of instances, and in some cases torticollis and asymmetry of the face and skull have been noted. One or more of the scapular muscles may be absent and bony anolamies are frequent. In a number of instances some congenital defect may be present elsewhere in the body. Chief among these are cervical ribs, spina bifida, deficiencies of ribs and vertebrae, displacement of spinous processes with fusion, fused and irregular ribs, and absence of ribs. In some cases a bridge of bone may connect the scapula and the vertebral column, in others there may be a long piece of bone projecting upward from the superior border of the scapula but not articulating with or attached to the vertebrae. In other instances there may be no bony outgrowths or deficiency of muscles. In some instances the projecting upper border of the scapula is so prominent in its elevated position that it is mistaken for an exostosis. Defective development of the muscles is common. The trapezius is the muscle usually affected. It is weak in all cases and occasionally it may be absent. The

serratus, pectoralis major and sternomastoid muscles are less commonly involved.

The symptoms are found in the asymmetry of the shoulders, the secondary changes in the spine, and often an inability to abduct the affected arm to its full extent. The scapula is elevated and rotated about its anteroposterior axis, so that its vertebral border, instead of being parallel to the spinous processes, is rotated so that the upper angle is nearer the middle line than the lower angle. The clavicle is frequently shortened, bringing the scapula and shoulder nearer the middle line. The upper angle of the scapula forms a prominent projection at the back of the neck. The chest is poorly developed, being narrow from side to side. In bilateral cases the dorsal and lower cervical vertebrae are prominent. In unilateral cases, the spines are frequently deviated, usually away from the affected side.

Treatment may be either conservative or operative. In cases seen during childhood extensive division of the shortened muscles holding the scapula in its abnormal position is to be advised. Removal of any bony bridge or projection and in

resistant cases resection of as much of the upper border as may be necessary should also be advised. In older cases no operative treatment is advisable. The conservative treatment consists chiefly of persistent gymnastics.

CASE REPORT.—The patient is a boy eleven years of age. He presented himself with a history of having fallen a short time previously. He fell from a fence, striking the right side of his chest against a stone. A week after the accident had been sustained his mother noticed that the right scapula was very prominent. The mother was positive that the deformity was not present previous to the accident. There is no doubt that the deformity was present throughout the life of the patient, and that the mother, being of the less observant type, did not notice it until the accident drew her attention to the condition.

Examination.—The right scapula was on a higher level than the left. The upper inner angle of this bone lies above the level of the clavicle and is three centimeters higher than the same angle of the left scapula. The upper inner angle of the right scapula is also slightly farther away from the midline than the same angle of the left, and slightly farther away from the midline than the lower angle of the same scapula. The vertebral border of the right scapula, therefore, instead of being parallel to the midline, as it should be,

is at an angle to it. The entire right scapula is rotated on an anteroposterior axis. The deformed scapula is rotated in the opposite direction, making the lower angle more prominent than it should be. The right shoulder is slightly limited in abduction. The right trapezius muscle is deficient, making the right side of the neck, posteriorly, shorter than the left. The right chest measures twelve inches, while the left chest measures thirteen and a half. The measurements were taken from the midline behind to the middle of the sternum at a level with the nipples. The lower angle of the right scapula was four inches away from the midline and the lower angle of the left scapula was two inches. The former was at the level of the fifth dorsal vertebra while the latter was at a level with the eighth. There was slight flattening of the right chest. The muscles on the right side were slightly atrophied. The right shoulder was slightly higher than the left. The radiograph showed a scoliosis in the middorsal region, which was also very evident clinically.

This case is undoubtedly one of congenital elevation of the scapula, in spite of the history given by the mother, namely, that it occurred after an accident sustained a short time previous to the visit to the clinic. As in many conditions where an accident attracts attention to a long standing pathological manifestation, so here the fall from the fence and the subsequent injury to the chest, drew the mother's attention to a deformity which had been present throughout the lifetime of the patient.

1182 JACKSON AVENUE.

Medicolegal Notes.

Memoranda Used by Medical Witness to Refresh Memory.—In a personal injury case a physician was called as a witness for the defendant. He treated the plaintiff on the night of the accident, a train wreck, and for the ten days she was in hospital. During that time he made two written memoranda as to the plaintiff's condition and treatment. He noted down the injuries found on her in the first one, and in the other the condition of the wounds when she left the hospital, as well as the troubles of which she then complained. The witness was permitted to use these memoranda when testifying, and after being so used the defendant offered them in evidence. They were excluded. On appeal this was held proper, as their only purpose in the trial, so far as the defendant was concerned, was to refresh the recollection of the witness, to the end that he might fully testify. There was nothing to show that they were kept, as books are kept, in the regular course of business.—*Willets v. Chicago, B. & Q. R. Co.*, Missouri Supreme Court, 221 S. W. 65.

Testimony of Habitual User Admissible That Substance Purchased Was Opium.—In a criminal prosecution for the illegal sale of opium, where the defense was that there was no evidence of a sale of opium, it was contended that the witness to whom the sale was made could not testify that the contents of the tins sold to him were, in fact, opium, as it required expert testimony to establish this fact, and the witness was not a chemist, or possessed of training in chemical analysis. The Circuit Court of Appeals held that, while it is true that, in order to establish the fact of the presence of alkaloid in opium, an analytical process must be followed, requiring the knowledge of the chemist to state positively that a substance is opium within the formula as defined by the United States Pharmacopoeia, the Government rightly contended that, it being established that the witness was a habitual user of opium, his testimony as to the nature of the substance with which he was familiar was sufficient to require the submission of the question of whether or not the substance was opium to the jury as a question of fact. One who drinks fermented liquor and knows the taste of it, although not a chemist, may testify that a particular liquor was fermented. *Merkle v. State*, 37 Ala. 139. A witness in a homicide case, familiar with the odor of carbolic acid, although not a chemist, may be permitted to testify that such

an odor came from the corpse. *Green v. State*, 125 Ga. 742. He may also testify to the odor of chloroform. *Miller v. State* (Tex. App.), 50 S. W. 704.—*Pennachio v. United States*, 263 Fed. 66.

Medical Witness May Disclaim Qualification as Expert on Special Point, Barring His Opinion as Evidence.—In an action for injuries caused by contact with an electrical wire stretched across a road in process of construction, the plaintiff claimed that his hearing and sight were affected. Over an objection by defendant, the court permitted a hypothetical question to be propounded to the physician who had examined and treated the plaintiff, for elicitation of an opinion as to whether the electric shock caused injury or impairment of his sight and hearing, with a view to augmentation of the damages, in case of recovery. There was evidence that, at some time before the injury, the wire had knocked a horse down. The question assumed that this accident happened the day before the occurrence involved in the case. It also assumed, without direct evidence, that the wire had struck the plaintiff on the forehead. He did not say what part of his body came in contact with it, but it might be inferred, from what he said, that it was some part of his head. Though the witness denied his qualification to give an expert opinion on the subject, he was urged to answer the question and said he thought such a shock might cause such an injury. It was held, on appeal, that the trial court should have sustained the objection to the question on the witness' disclaimer. Physicians are not, as matter of law, qualified to give opinions, as experts, upon all medical questions. There are many instances in which their testimony has been rejected. A general practitioner has been held not to be qualified as an expert upon questions pertaining to a branch of medical science to which he had given no study and concerning which he had had neither observation nor experience. *Russell v. State*, 53 Miss. 367; *Emerson v. Gaslight Co.*, 6 Allen (Mass.) 146. Disclaimer of qualification to testify on the subject of the interrogation, by the witness himself, rendered his testimony incompetent. It was therefore unnecessary to inquire whether the question was properly framed.—*Fisher v. Flanagan a Coal Co.*, W. Va. Supreme Court of Appeals, 103 S. E. 359.

Ordinance Providing for Milk Pasteurization Upheld.—The Wisconsin Supreme Court holds that an ordinance of Milwaukee requiring milk sold in that city, except certified milk and tested milk, to be pasteurized by the holding or the flash system, is a regulation for protection of the public health, within the discretionary power of the council.—*Pfeffer v. City of Milwaukee* (Wis.) 177 N. W. 850.

Ohio State Medical Act Held Within Police Power of State.—The Ohio General Assembly is held to have the right to reasonably regulate business and occupations and those desiring to follow them, especially physicians and surgeons; and legislation of this character is within the police power of the State upon the further and higher ground of the regulation of public health. All persons engaged in the practice of the healing art need special qualifications touching the knowledge of the human body in all its parts, their normal and abnormal relations—not only knowledge that would enable all such persons carefully and correctly to diagnose physical and mental ailments, but also an ability to prescribe the proper treatment therefore. The State Medical Act, requiring a license to practice medicine, is therefore held clearly within the police power.—*Nesmith v. State*, Ohio Supreme Court, 128 N. E. 57.

Practising Without Certificate Under California Medical Practice Act.—The title of the California Medical Practice Act, reading "An act to regulate the examination of applicants for license, and the practice of those licensed to treat diseases, * * * to establish a board of medical examiners * * * and to repeal an act entitled 'An act for the regulation of practice of medicine' etc., is held sufficiently comprehensive to include provisions as to punishment of a person holding himself out as entitled to practice medicine, without having a certificate under section 17, and is therefore not unconstitutional. An information, otherwise in proper form, in a prosecution for violation of this section, is sufficient as against the contention that it does not give the name of any patient or disease treated.—*People v. T. Wah Hing* (Cal.), 190 Pac. 662.

TREATMENT OF THE HUMAN BREAST.

OPERATING upon the breast without absolutely sufficient reason is bad surgery. Therefore accurate diagnosis is the essential part of the physician's or surgeon's equipment, for without this gift or skill acquired by practice, there is no doubt that a certain number of unnecessary operations will be performed. It is a fact that the good diagnostician is, to a large extent, born, not made, although it is equally true that this inborn characteristic can be greatly improved by practice. The necessity for accurate diagnosis is in no class of operation more evident than in the surgery of the breast, as from every point of view it is a very grave matter to remove or mutilate the breast or breasts of a woman and especially of a young woman.

In a paper published in the *Medical Press and Circular*, Feb. 2 and 9, 1920, Commander W. Seaman Bainbridge, M. C., U. S. N., discusses this question in its various bearings. He allows that, if a lump appears in the breast, a medical man, or a specialist rather, shall be consulted with as little loss of time as possible, but the verdict upon which hinges the decision as to the steps to be taken should be given only after mature consideration of all the evidence available. It must be borne in mind that some disagreement exists among authorities on essential as well as non-essential points in this respect, and the remark quoted by Bainbridge of a well-known author that "the platitude that it is better to sacrifice a dozen suspected breasts than to overlook a single case of carcinoma has long served as a cloak for ignorance of the finer pathological changes in the gland," is in the main correct. The statement pleading for a measure of conservation contains more than a grain of truth. There are several conditions which simulate malignant disease of the breast and these should be noted and considered carefully before making a diagnosis and coming to a decision. Bainbridge refers to the breast lumps caused by intestinal stasis, to which Sir Arbuthnot Lane was the first to call attention, and gives several instances drawn from his own experience of breast changes thus originating which were cured by conservative operation or rational treatment. A strong warning is given against

biopsy for the purpose of pathological diagnosis. Of course, it is obvious that if this is done and the disease is really malignant such a dissemination of the cancer may follow this ill-advised procedure that a subsequent operation will be useless.

The various points made in this excellent paper are mainly as follows: As a result doubtless of the efforts of the Society for the Control of Cancer and other organizations the laity is seen to be coming early in increasing numbers for examination. Accurate diagnosis of abnormal breast conditions means and demands a careful systematic survey as well as an efficient local examination. The relationship between chronic intestinal stasis and certain breast conditions seems to be proved. Toxemia from teeth, tonsils, and other parts of the body, may also have its effect upon the mammary gland. Abnormal conditions, congenital or acquired, may be present in neighboring structures and lead to wrong diagnosis of cancer, or if malignant disease is present, lead to the diagnosis of the inoperable and incurable stage, although the neoplasm is early and surgically curable. In spite of present knowledge it is impossible at times to arrive at an immediate accurate diagnosis. In justice to the patient it may be necessary to keep her under careful observation, treating general conditions before proceeding to radical surgery. If mistakes even then occur, it should be the earnest endeavor of the profession to make them fewer and fewer. Bainbridge, like most surgeons, believes that when cancer is present beyond a reasonable doubt, radical surgery is indicated, but he urges, nevertheless, that *festina lente* should be the motto when dealing with breast tumors. Although accurate diagnosis may be frequently extremely difficult, sometimes almost impossible, a hasty operation for fear that the condition may be cancer should not be undertaken lightly.

It is refreshing in this age of the knife, when some would cut away every skin blemish lest in the indefinite future it may become a malignant tumor, to learn that even among the surgeons there is at least one who would withhold the knife until its use is, in his judgment, plainly indicated. It suggests the belief that some day the recognized indication for a cancer operation will be mechanical or cosmetic and not the expectation of a cure.

PHOCOMELIC MONSTERS.

A PHOCOMELUS monster is an ectromelic being whose hands and feet appear alone to exist and as if directly inserted on the trunk. This definition requires amplification and more precision. Let it be recalled in the first place that ectromelia is characterized by the more or less complete absence of one or more limbs. Now, it is known that the free portion of every limb in vertebrate animals is composed of three segments: a terminal one—hand or foot—the other two being intermediary, one being proximal—arm or thigh—the other distal—forearm or leg. The ectromelics in whom abortion occurs in the intermediary segments, are phocomelics; those in whom the abortion takes place in terminal

segment are hemimelics, and finally when the entire member has completely aborted, the case is one of entromelia. The first two types may be combined, giving rise to another category, hemiphocomelus. Consequently, the following definition can be offered: Phocomelus is a monster characterized by a more or less complete abortion of the intermediary segments of the limbs. Individuals affected by this anomaly consequently have normal hands and feet attached to the trunk by very short atrophied segments. Such is the arrangement normally observed in certain digging animals—moles—or swimming animals—seals—hence the term phocomelus created by I. Geoffroy Saint-Hilaire.

Phocomelia may involve all four limbs, in which case it is quadruple. It may be limited to the two upper members—bithoracic phocomelus—or to the two lower limbs—bipelvic phocomelus. Or the two limbs on the same side are the seat of the congenital defect—unilateral phocomelus, and finally a single upper or lower limb may be involved, in which case there is unithoracic or unipelvic phocomelus. In each of these forms the abortion of the intermediary segments is more or less pronounced. With Broca, we should note the fact that the word *abortion* as used here is not synonymous with absence, and usually there are very appreciable traces of the aborted intermediary segments, while in the less characteristic forms one may well hesitate to recognize true monsters. Phocomelia offers various degrees, from types solely characterized by a shortness of the intermediary segments up to their apparent complete absence.

It is natural to suppose that to each of these degrees a different anatomical structure should be found. The bones, muscles and other soft structures of the intermediary segments are all the more atrophic and reduced in extent the more the higher degrees of the defect are reached. But it must not be assumed that this reduction occurs in identical proportions of the different component elements of the intermediary segments. It will be found on the contrary that the anatomical structure of the various cases of phocomelus give rise to unexpected general considerations which have only recently been brought into relief. This congenital defect is perfectly compatible with life and the majority of these beings who attain adult life are endowed with perfect physical vigor and occasionally a mentality superior to the average. By a long and careful education these defectives can use their rudimentary limbs with considerable agility and some may even perform feats that cannot be accomplished by normal beings. There is usually no disturbance of the sensibility, no loss of muscular sense, nor any paralysis of the subsisting muscles.

The classical writers tell us little in respect to phocomelus, being content with invoking an arrested development as the cause, which certainly is vague, and comprises the most diverse teratologic phenomena. Even the cause of arrested development has been searched for in atavism, compression on the annios, a primary defect of the cerebrospinal axis, or even a circular of the cord around the

neck. But no observer has described any peculiar process ending in the production of phocomelic monsters, so that one is tempted to admit at first sight that phocomelus is merely the result of an arrested growth of the intermediary segments of the limbs. This, however, is not usually the case, the condition being due to complex processes. In 1898 Virchow emitted some very important considerations; he comprised under the same denomination of phocomelus all ectromelics, because for him they represented the most characteristic term of this category of monster. He placed the ectromelics in a continued series whose different terms are the degrees in a scale of a pathological malformation, Kauffmann's chondrodystrophia fetalis being the nearest type. Consequently, according to Virchow, these beings are not monsters, but defectively developed subjects. This conception of phocomelus has not been confirmed by others and all that Virchow did was to consider the condition as having its starting point in a localized affection of the osseous system. Although we cannot accept Virchow's opinion in its entirety, it may nevertheless be admitted that the majority of phocomelic monsters are merely achondroplasias, a theory most compatible with the present state of our knowledge.

MUST WE ALL BE LAW-BREAKERS?

THE average physician, we would fain believe, is not naturally a criminal, but since the uplifters have begun to regulate the practice of medicine and to determine what remedies the doctor can prescribe and in what doses he can give them, he is rapidly and perforce becoming one. He is forbidden to prescribe narcotics in certain cases and in others he must be careful not to give them too frequently or in doses which the lay bodies who are watching him may decide are too large. Moreover he can't prescribe narcotics in any case unless the revenue departments, national and State, sell him permission to do so, and then it is only after he has filled out half a dozen blanks and gone through various tedious formalities that the pharmacist dares honor his prescription. And even then he may find that some commissioner or other has made a new ruling so that he has become unwittingly a law breaker over night. A physician of this city, a practitioner of over thirty years' activity, writing in the *New York Times*, says that there are two sets of narcotic laws and sixteen regulations based upon them, but he overlooks the fact that these sixteen regulations refer to only one of the laws, and how many regulations there may be to-morrow or the next day, when some dreamy clerk wakes up with a new idea, relating to the other law nobody knows. The writer truly remarks that if all the laws were strictly enforced—and they might be any day if some deputy were suddenly to realize that he or she was not earning his or her wages—only a retired physician would be safe from jail.

Then there is the prohibition law. Any well man in New York City, and we presume elsewhere, who wants a drink and has the price can get it, but

the sick man whose health or life may depend on it can whistle with what breath is left in his body and won't get it. Owing to the vexatious formalities required of a physician seeking for a permit to prescribe alcohol, to say nothing of the insults to which he is liable from some swollen headed clerk or spy, comparatively few practitioners are able to prescribe the drug for their patients, and even these are restricted in the amount which they can order, the dose being limited to an average of twelve teaspoonfuls a day. The correspondent of the *Times* above referred to, claims that he is really not criminal in his instincts or habits, but says that he cannot practise his profession without doing perhaps petty but really criminal things. He states further that he has been trying for nearly nine months to get a permit to have pure ethyl alcohol for surgically external use in his office. "I have been visited," he writes, "by two inspectors, who examined my professional outfit and asked about my professional career. I have signed and sworn to various documents testifying to my correctness of life, etc., but I have no permit and must infer I am unfit." He doesn't say so, naturally, but we have little doubt that he has obtained the alcohol he needs by some criminal act. It was William H. Seward, we believe, who said that "there is a higher law than the Constitution."

There is a bill before the New York Legislature repealing the narcotic drug law of the State, which we hope will pass. (It is the Lord bill to which we refer, and not the Smith-Fearon bill.) The Harrison law with some amendments will be sufficient to restrict the traffic in these drugs without forcing the mass of the profession into the ranks of evaders, if not breakers, of the law.

CAN THE BLIND SEE?

CANTONNET, the well known ophthalmologist, asks this question in all seriousness in *La Presse Médicale* for December 8, 1920, xc, 90. By "blind" is meant actual loss of the eye bulbs, as in the result of double enucleation, and by "see" is connoted the ability to distinguish forms, dimensions, colors, etc. Hypnotists have often asserted that some subjects can read books placed against the chest or cranium, and in such cases thought transference has been excluded. Recently Farigoule has published a book on extraretinal vision in which he describes new experiments on the hypnotized with bandaged eyes. Some of these are striking, and after some delay the subjects have described and identified objects placed not only in front of the eyes but elsewhere on the surface. The practical end of this subject is the possibility of restoring sight to recently war-blinded victims. Cantonnet has thus far tested four blind men, all but one being war blinded. With two of these the result was absolutely negative after 12 or 14 hours of trial. A third gave also a negative result, although the duration of the experiment may have been too short. The fourth patient was a civilian aged 59, a medical colleague endowed with great faculty of analysis and perseverance. The trial lasted 45 hours but there was not so much

as a perception of light obtained. Nevertheless, Cantonnet does not abandon hope, since others have reported positive results. In Boirac's recent work on unknown psychology a hypnotized subject is said to have read print too fine for ordinary eyesight and in the absence of illumination.

DURATION OF PREGNANCY.

LABOURÉ writes briefly on this subject in *Le Progrès Médical* for December 4, 1920, xlviii, 50. He refers to a recent article by Vignes which claims that the difficulties in evaluating the length of a gestation are manifold. Vignes cites the interval between the Feasts of the Annunciation and Christmas, and certain episodes in mythology in the research for the earliest attempts at this computation. But it is universally admitted that the length of normal gestation shows much variation. The averages have been 9 solar or 10 lunar months—274 to 280 days, but the real unit should be the ovarian cycle. This varies from 27 to 30 days, according to the woman. In case 10 is the multiplier we would have 270 days for the first type, 300 for the last type, and others between. But while the ovary determines menstruation we do not know that it also determines the time of labor. There is a field here for exhaustive study—for comparison in healthy women of the ovarian cycle with the duration of gestation. The latter would also have to come up to a certain standard of perfection. But it is usually difficult to fix the date of the fecundating coitus and even impossible at times to determine within a day or so when labor really begins. An unknown component is the time required for the semen to reach the tubes; for while this may take place within a few hours as shown in special cases of violent death, we do not know the average interval. To fix the moment at which the spermatozoon enters the ovum is of course quite impossible, and it would be more practicable to fix the period of embedding which appears to be the first actual beginning of gestation.

MASTOIDITIS AND SUBOCCIPITAL POTT'S DISEASE.

PORTMANN of Bordeaux contributed a monographic article on the above named subject in the *Revue de Chirurgie* for September-October, 1919, xxxviii, 9-10. The subject is on the border line between surgery and otorhinolaryngology. The author finds that the question of differential diagnosis between the two above named affections has been much neglected. Failure to make the correct diagnosis might in either mistake prove disastrous. Suboccipital Pott's has repeatedly been diagnosed as mastoiditis, but the medical men who make the mistakes do not always publish them. Moure of Bordeaux has seen two cases and the present author one, which is described. The differential diagnosis applies to three separate conditions: (1) An abscess has not formed; (2) there is a cervical abscess; (3) there is a fistulous tract. If there is no abscess forming as yet, auricular symptoms point to mastoid disease and absence of such symptoms to Pott's. Stiff neck in mastoiditis is usually absent or at best very slight, while it is a marked symptom of Pott's disease. In Pott's the mastoid region

shows no deformation. Pain, both spontaneous and induced, is referred to the affected region. After abscess formation has occurred, the pain in Pott's is not conspicuous, while in mastoiditis it is pronounced and unilateral. In Pott's we have a "cold," in mastoiditis a "hot" abscess. Punctates show the characters of the two types. If not seen until the fistulous stage the fistula presents the characters of tuberculosis in the Pott's patient and that of a phlegmon in the other. Both the radiograph and the probe should be decisive.

News of the Week.

Hearing on Amendment of Compensation Law.—Little opposition was expressed at the public hearing in Albany on March 2 to the Burlingame bill amending the workmen's compensation law to provide medical treatment for injured employees at the expense of employers and empowering the commission to fix minimum fees for surgical and medical attendance. The measure was opposed by the State Industrial Commissioner, Henry Sayer, who suggested that a legislative committee be appointed to study the medical question so far as it related to workmen's compensation. Representatives of the State Federation of Labor spoke in favor of the bill.

A Case of Typhus Fever at Massena, N. Y.—A case of typhus fever was reported to the State Department of Health from Massena, St. Lawrence County, on March 2. The patient, a Hungarian woman, arrived at New York, Feb. 6, from Rotterdam. The vessel on which she came was detained at Quarantine for ten days. She arrived at Massena Feb. 16 and was taken ill a week later.

No Special Appropriation for Quarantine.—On March 2 Congress was asked to appropriate \$1,291,330 with which to fight typhus fever at the Quarantine stations at Boston, New York, Baltimore, and Philadelphia. In explaining the need for this appropriation Surgeon-General Cumming stated that the accommodations at Hoffman's Island had not been increased materially for the past twenty years, and are only sufficient for the detention of about 1,500 persons. There is at present no water supply at Hoffman Island, the water being supplied by lighters. The cost of properly equipping the station is estimated at approximately \$500,000. Congress adjourned without making the appropriation.

Doctors Turn Over Wartime Profits to Science.—The sum of \$500,000 has been given by Dr. Jay Frank Schamberg, Dr. John A. Kolmer, and Prof. George H. Raizess to the Dermatological Research Laboratory of the University of Pennsylvania. This sum represents the profits received by the laboratories during the war from the sale of arsphenamine. For more than a year after the German supply was cut off this was the only laboratory in this country supplying the drug. It was sold for about one-third less than the usual price of the German product and was supplied in great quantities to the Army and Navy. In turning the money over to the laboratory, Dr. Schamberg said that he in no sense regarded the half million dollars as a gift; he felt that it belonged to the laboratory; that he was simply going

through a legal process to turn it back to them. The Dermatological Laboratory has discontinued the manufacture of arsphenamine and resumed its scientific work along the lines which it originally followed.

Lay Cornerstone of New Hospital.—The cornerstone of the new Beth David Hospital at the corner of Lexington Avenue and One Hundred and Thirteenth Street, New York, was recently laid. This ceremony marked the opening of a campaign to raise \$150,000 needed to complete and equip the new building. The hospital has recently opened a new clinic and dispensary with a staff of twenty-six physicians and surgeons, at a cost of \$51,000.

United States Public Health Service Hospitals in Pennsylvania.—Plans prepared by the United States Public Health Service and about to be put into effect will largely increase the hospital facilities for ex-service men in Pennsylvania. At Pittsburgh the capacity of Marine Hospital No. 15 will be trebled at first by the addition of a dozen portable buildings of approved type, and later, when Congress appropriates the necessary money by permanent construction. At Philadelphia the United States Public Health Service has recently acquired from the Navy a large hospital for the care of ex-service men suffering from nervous and mental diseases. Its capacity is between 400 and 500. It is hoped that this hospital will become permanently devoted to work of this kind.

Public Health Service Gets Rutland Sanatorium.—The model tuberculosis sanatorium nearing completion at Rutland, Mass., originally established by the New England Sanatorium Association, has been leased for a term of years by the United States Public Health Service. Within two months it is expected that the hospital will be able to accommodate 100 patients and that it will ultimately care for 300. The finished building will be the last word in tuberculosis. The surroundings are ideal, and the ex-service men who will shortly fill this hospital will be assured of the best that modern science can provide.

Survey of Government Sanatoriums.—Eminent tuberculosis specialists who, at the request of Surgeon-General Cumming of the United States Public Health Service, have been visiting the tuberculosis hospitals of the service, have completed their task and submitted their suggestions. Steps to put into effect their suggestions were immediately taken and are already in operation in part. Those who made the survey are: Dr. David Lyman of Wallingford, Conn.; Dr. Victor Cullen of the Maryland State Sanitarium; Dr. Martin E. Sloan of Towson, Md.; Dr. George Thomas Palmer of Springfield, Ohio, and Dr. Henry Hoagland of La Jolla, Cal.

Community Hospital Unaffected by Action of Board of Regents.—According to an announcement made by Dr. William H. Diefenbach, president of the Community Hospital, New York City, the recent action of the State Board of Regents in removing the trustees of the New York Medical College and Hospital for Women will have no effect on the Community Hospital, which operates under a charter from the State Board of Charities. The college ceased to operate in 1918 and its charter was surrendered last year.

Hospital Cuts Wages.—The New York Post-Graduate Hospital has reduced the salaries of its 250 employees approximately 20 per cent., and as a result some 75 to 100 employees have resigned. In making this reduction the directors of the hospital state that the reduced wages compare very favorably with those paid in similar institutions. Six internes who received no salary, but only board and lodging, have also been dropped. It is said that by these salary decreases the institution expects to save about \$1,000 a month.

Campaign Against Cancer.—During the week beginning March 7 a series of mass meetings to control cancer were held in New York City through the cooperation of the American Society for the Control of Cancer, the New York City Department of Health, and the Board of Education. The meetings were held in various public school buildings throughout the city and were designed to educate the general public in the necessity for the early recognition and treatment of cancer.

In Memory of Elizabeth Blackwell.—A stated meeting of the Women's Medical Association of New York City will be held on Wednesday, March 16, at the Academy of Medicine, at 8:15 P. M., to honor the memory of Dr. Elizabeth Blackwell, pioneer woman physician of America, on the 100th anniversary of her birth. Papers will be read by Drs. Sarah J. McNutt, Ethel Blackwell Robinson, and Annie S. Daniel.

A Hearing on the Narcotic Bills.—A public hearing was held in Albany on March 8 on the three narcotic bills now before the Legislature. The opposition was centered chiefly on the Smith-Fearon bill, which would result in herding all addicts into institutions or forcing them to look to the underworld for the drug which they cannot do without. The bill was supported by the Medical Society of the County of New York, represented by Dr. W. P. Healy and opposed by the Medical Society of the State of New York through Dr. James A. Rooney of the legislative committee. It was also opposed by Dr. John P. Davin, Judge Cornelius J. Collins and others. Judge Collins took occasion to score the Health Commissioner of New York City for the cruel registration rule, which he said drove addicts to stand in line before the Narcotic Commissioner's office for the delectation of "rubber-neck" tourists.

English Village Holds Age Record.—A correspondent of the London *Daily Mail* writes that Dawes Heath, in Essex, a little town not on the railroad map, probably holds the record as regards number of aged inhabitants. In this village there are twenty people of eighty years or more, three of ninety or more, and any number of stripplings of seventy and youths of sixty or more. Everyone is expected, except by some dire mischance, to live at least until he is eighty. One energetic young woman of eighty-three, when asked why they were all so old and so well, replied that perhaps it was hard work; that it was her habit to rise at six in the morning and to keep busy until eleven or twelve at night.

Alcoholic Liquors in Patent Medicines.—Attorney-General Palmer has ruled that whiskey and other liquors may be used in the manufacture,

under permit, of certain patent medicines and toilet preparations. The products in which, under the ruling, whiskey and other liquors may be used are medical preparations manufactured in accordance with formulas prescribed by the United States Pharmacopeia, patent and proprietary medicines unfit for use as beverages, and toilet, medicinal, and antiseptic preparations unfit for beverage purposes.

Rear Admiral Cary T. Grayson has been ordered by the Navy Department to duty as officer in charge of the Naval Dispensary in Washington. It is stated that he will continue to be the personal physician of ex-President Wilson.

Dr. D. L. Rauch has removed his offices to Hotel St. Margaret, 129 West Forty-seventh Street, New York.

Dr. Leon Becerra, chief health officer of Guayaquil, Ecuador, and member of the Commission of the Rockefeller Institute studying the yellow fever situation, died on March 3 of injuries received in a street car accident.

The Second International Congress of Eugenics will be held in New York City, September 22-23, 1921. All communications concerning the meeting must be addressed to the Secretary-General, Dr. C. C. Little, American Museum of Natural History, 77th Street and Central Park West, New York City.

Professional Guild Organized in Chicago.—At a meeting held in Chicago on February 23, following an address by Dr. John J. O'Reilly of Brooklyn, an organization of doctors, dentists, and druggists was effected along the lines of the Professional Guild of Kings County. It has for its object the protection of the medical, dental, and pharmaceutical professions against the socialization of medicine and to keep the safeguarding of the public health out of machine politics.

Women Recover Control of Medical College.—The Alumnae Association of the New York Medical College and Hospital for Women announces that the State Board of Regents has removed the Trustees of the college, thus bringing victory to the group of women physicians who have sought to recover control of the institution from men physicians. The hospital building is now occupied by the Community Hospital and it is stated that control of the hospital building will probably become a matter of litigation.

The Parkin Prize.—The Royal College of Physicians and Surgeons of Edinburgh announces that the Dr. John Parker Prize of one hundred pounds sterling is open to competitors of all nations. The subject of the essay for the present period is "On the Effects of Volcanic Action in the Production of Epidemic Diseases in the Animal and in the Vegetable Creation, and in the Production of Hurricanes and Abnormal Atmospheric Vicissitudes." Essays intended for competition must be written in the English language and must be received by the Secretary, Dr. J. S. Fowler, not later than December 31, 1921. Each essay must bear a motto, and be accompanied by a sealed envelope bearing the same motto outside and the author's name inside.

Gifts and Bequests.—The value of bequests to charitable institutions made by the will of the late Henry Clay Frick has greatly depreciated since the testator's death, and according to estimates made

in Pittsburgh, where the will was probated, are as follows: Children's Hospital, Pittsburgh; Allegheny General Hospital, Home for the Friendless, Pittsburgh; Kingsley House Association, Pittsburgh; Mercy Hospital, Pittsburgh; Pittsburgh Free Dispensary, Western Pennsylvania Hospital, Pittsburgh; Uniontown Hospital, Fayette County, Pa.; Cottage State Hospital, Connellsville, Pa.; Mount Pleasant Memorial Hospital, Westmoreland County, Pa.; Westmoreland Hospital, Greensburg, Pa.; Braddock General Hospital, Allegheny County, Pa.; Homestead Hospital, Homestead, Pa.; each \$200,000; the Lying-In Hospital of the City of New York, \$600,000.

The will of the late Helen F. Massey of Philadelphia makes the following bequests: Hospital of the Protestant Episcopal Church, \$500,000; Pennsylvania Hospital, \$500,000; Pennsylvania Society for the Protection of Children, \$300,000, and the Gyncecan Hospital, \$150,000.

The Officers and Councillors of the American College of Physicians, held at Baltimore, February 25, 1921, elected the following officers: *President*, Dr. James M. Anders, Philadelphia, Pa.; *Vice-President*, Dr. Frederick Tice, Chicago, Ill.; *Second Vice-President*, Dr. C. C. Bass, New Orleans, La.; *Secretary General*, Dr. Frank Smithies, Chicago, Ill.; *Treasurer*, Dr. Clement R. Jones, Pittsburgh, Pa.

Vacancies for Physicians.—The New York Civil Service Commission announces a vacancy in the State Institute for the Study of Malignant Disease, Buffalo, for an internist, at a salary of \$2,500. Candidates must be physicians who have had not less than two years' experience in a recognized hospital of high standing. This is strictly a research position. A vacancy for a psychiatrist at the New York State Reformatory for Women is also announced. The position carries a salary of \$3,000 and maintenance. Candidates must be physicians with special experience in psychiatry. Application forms will not be sent out by mail after March 14 and may not be accepted after March 16. For the application form address the Civil Service Commission, Albany, N. Y.

New York Academy of Medicine Increases Non-Resident Membership.—At the stated meeting of the New York Academy of Medicine, held March 3, 1921, the recommendation of the Council that the Constitution be amended so as to increase the number of Fellows not residing in the city of New York from 250 to 300, was adopted.

Obituary Notes.—Dr. FRANK A. MCGUIRE, physician at the Tombs Prison, New York, for twenty years, died of heart disease at his home, on February 28, at the age of sixty-seven years. He was a graduate of New York University Medical School in 1877. He was appointed physician to the Department of Corrections soon after graduation.

Dr. WILLIAM FISKE WHITNEY, Curator of the Warren Anatomical Museum at Harvard University, died at his home in Boston, on March 4, at the age of seventy-one years. He was graduated from the Harvard Medical School in 1875.

Dr. RALPH C. KLEPSEK of Altoona, Pa., died on February 21 at the age of sixty-five years. He was graduated from Bellevue Hospital Medical College in 1878.

Correspondence.

LETHARGIC ENCEPHALITIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—We are apparently in the beginning of an epidemic of encephalitis lethargica (sleeping sickness). Several things stand out. First, it is evidently infectious or contagious. Secondly, we do not know the mode of transmission. Thirdly, there is no positive information as to the specific causative factor responsible for the disease, consequently there can be no specific serum treatment. The pathology of the disease indicates an unquestionable infection as shown by Marinesco and Mott, closely resembling the pathological changes demonstrated in the recent influenza epidemic, and therefore it may possibly be due to the same organism. Until the discovery of a specific germ, there can be no specific treatment.

It would seem, in view of the evidence submitted by McDonaugh, that the body produces certain non-specific substances on which it naturally depends for defence against infections of all kinds, and which his investigations seem to prove are capable of being stimulated to increased activity by certain metals. In combating infectious diseases to which "sleeping sickness" evidently belongs this natural defence of the body should be made use of. Metals, especially in colloidal form, do this and should be employed at a time when we have no specific treatment, because it is working along the lines of stimulating or assisting the natural resisting powers of the individual, while symptomatic treatment, used to remove symptoms to make the patient more comfortable, seems to be not only of doubtful value, but possibly harmful when the tissues to be acted on, owing to their diseased condition, are not capable of responding. Therefore material injury may accrue to the patient for the reason that, the cause not being understood, the treatment is directed solely to the symptoms. Colloids of several metals, gold, silver, manganese, etc., properly applied stimulate the protective resources of the body and consequently assist the patient to recovery.

W. B. HOLDEN, M. D.

2131 BROADWAY, NEW YORK.

WHY IS A NARCOTIC COMMISSION?

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—An initial appropriation is a latch-key to the Deficit Door of the State Treasury. How true this is can be measured by the history of the Narcotic Commission which grew out of the Whitney investigation in December, 1917, and which comes before the people this year with a request for more than a quarter of a million dollars.

Why is this Narcotic Commission? Because there was not enough statesmanship in the whole State of New York in 1916 to write into the Statutes the Harrison Law and make possible the cooperation of the Federal and State authorities in striking at the various sources of supply through the American manufacturers and across the Border and by way of our Port of New York, instead of playing at cross-purposes, each jealous of the other and both making a mess of things.

Why is this Commission? Because when legislators want to be kept busy, after sessions, at the expense of the State, they put through a Commission and go about the State "investigating."

Why is this Commission? Well, a lady came from England, who was believed to represent an association which had purchased the rights to the Normyl Cure for drug addiction; this lady was taken up by some leaders of society and was designated a deputy narcotic commissioner and things went on for some time, the Commission as inactive as if it were narcotized and the new cure for drug addiction progressing actively, thank you. . . . And all this time there was tucked away in the law which gave the commission existence one of those cute provisions which empowers the commission to make "regulations" and to invest them with the "force and effect of statute," and on December 27, 1920, this commission made some utterly absurd regulations which prompted a mass meeting of doctors, dentists, and druggists in Kings County and afforded the lady deputy narcotic commissioner a chance to invite herself to the party and tell us that 20 per cent. of the doctors in the State of New York (one out of every five) indulged in the indoor sport of creating drug addicts and that the doctors had the harsh voice for the poor addict and the gentle voice and considerate attitude for the rich addict, and that we should cooperate with her commission and equip ourselves with duplicate and triplicate prescription books in order that we might write for so small a quantity as a millionth of a grain of codeine to a gallon of cough mixture, or any quantity of codeine's big brother, morphine, to infinity in both directions, whether it was intended to relieve the ordinary ills of man or the disease called drug addiction which, by some hocus-pocus, has been designated a "pestilential disease" in order to provide the citizens of New York with the very distressing picture of a snake line of unfortunate addicts in Centre Street. Well, that 20 per cent. statement is subject to one of two deductions—that there are 3000 medical prostitutes in the State of New York or that the charge is inexcusable. When the man in the street is making his choice of deductions he will please bear in mind the type and degree of self-sacrifice and devotion of the doctors of his State, in peace and in war, and per contra the fact which stands out like a sore thumb that the Normyl cure is a strictly proprietary remedy the property rights in which are held in England.

Why is this Narcotic Commission? To make it difficult, if not impossible, for a decent, self-respecting doctor to use, without risk of jeopardizing a reputation it has taken him years to construct, a class of drugs which have unquestionable value.

. . . It is all very well for this Commission to tell the public that it is after the panderers and rascals in the medical profession, but, as Grover Cleveland said: "It is a condition and not a theory which confronts us;" when it is possible for an official to deliberately charge the medical profession as a class with treachery to their order to the extent of 20 per cent.; when it is possible for a doctor to be arrested and put to the embarrassment and expense of his defense because he has made a mathematical miscalculation (People vs. Hoyt) and, after this is demonstrated to a chemist attached to the Depart-

ment of Correction (since dead) and detectives of the drug squad (still living), instead of an honorable apology for an over-zealous mistake, the doctor's medical counsel is informed, "If you beat us on this we will get him on something else." In view of this and of subsequent events the profession of medicine is warranted in believing that "the higher one is, the farther one falls" and in refusing, under the law of self-preservation, to treat an unfortunate victim of drug addiction by any method which includes the use of the sustaining drug, leaving him to the care (God save the mark) of the "experts" in drug addiction in the private sanatoria or to the mercy of institutionalism, which is precisely what the "uplifters" want.

Why is this Narcotic Commission when there is a "Lord Bill" before the Legislature which would abolish it and put the responsibility where it properly belongs, with the peace officers of the State and the local health departments and the agencies of healing, public and private? Then, this legislative excrescence being obliterated, *write into the statutes the Harrison Law* in its entirety and put it up to the police to round up the panderers, lay and medical, and to the Federal authorities to protect the border and follow the drugs right into a municipality where, instead of friction, they may find co-operation by the peace officers; putting it up to the medical profession to study and solve the problem, as individual practitioners and as groups in their hospitals and medical societies; protect the sick citizen in an honest endeavor to rid himself of his curse by throwing every safeguard around the honest doctor who is trying to help him. Don't make him feel the law is his enemy that will pick him up and stick him away and, after a week or ten days, send him forth "cured" whereupon some smug "uplifter" gives him the "right hand of fellowship" as he departs and with his left index finger points him out to a "gum shoe" man who will "check him up" in his home and place of occupation, regardless of his domestic privacy, self-reliance, and self-respect. Give the poor victim a chance; they can do it in Boston, why not here?

Personally I have no use for the "gradual reduction" method or the substitution of "pilocarpine" to produce what the poor victims call the "spitting and sweating" stage, but neither that fact nor the fact that I have not dispensed or prescribed any of these drugs in years (I am not conceited enough to believe) furnishes any argument against their proper use. I believe firmly in what the Bostonians call the "cold turkey" plan. The district attorney, acting in concert with the health authorities, receives an addict for treatment under any old name, John Doe, Richard Roe, etc., so as to preserve his pride of self and family; he is treated as a man who desires relief and not as a *thing* which deserves a blow; he is put to bed and by chologogue and mild cathartic and saline enemas thoroughly cleaned out, and then he is supplied with highly nutritious food, in small quantities, frequently repeated, and the tired, exhausted heart-muscle is watched and needful stimulation applied until he begins to get his percentage of tone from the digestion and assimilation of his food material. Of course he suffers some pain, but the fear which intensifies that pain is allayed because he is taken into the confidence of the

doctor and made to understand that it is due to body-waste producing irritability of his musculature and the nerves of sensation and if he will give nature a chance she will clean up shop. Then, above all other things, he is impressed with the fact that the doctor is the professor (who teaches), the man is the doctor (who practises), and the body is the patient, and upon their cooperative work depends the result. The personal equation is aroused by this man-to-man method and the records show that *they do not die* but get well and stay well and act as missionaries.

Here is no proprietary nostrum; here is no ad-dict-baiting for the sake of a record of arrests; here is a situation with which the medical man must be in sympathy; here is a condition which can be brought about in New York State just as soon as we get rid of an overlapping narcotic commission and awake to the narcotic situation as a disease—not pestilential which calls for an exhibition of unfortunates on the city's streets; not criminal, save in some instances in the underworld; but a purely physical condition of disordered chemistry which hysterical propaganda has made into a hopeless slavery. "Let's play the game," as Polyanna says, and be glad that Boston has shown us the way and go to it by passing the "Lord Bill," writing the Harrison Law into the Statutes; locking up and forcibly treating the vicious addict from the underworld; apprehending the panders, lay and medical, and shutting off their source of supply; letting the sincere victim turn with confidence to his family doctor and the family doctor, under the protection of law, do his level best in the home or in the hospital to restore the victim to health and civic and economic usefulness; save the patient's personal pride above all things and treat him as a man! but get rid of that commission that has not done a constructive thing since the unfortunate day it was born; the gratuitous insult to the people's agencies of healing bars any possible cooperation between men and women of medicine and lay commissioners, male or female, who proceed on the theory that the commission's the thing and the profession of medicine its Man-Friday to submit to fool regulations which have the force and effect of laws and to kiss the hand that issues them.

JOHN J. A. O'REILLY, M. D.

405 UNION STREET, BROOKLYN, N. Y.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, February 15, 1921.

Post-War Marriages.—An official of the Registrar-General's Department at the Ministry of Health informed a representative of the *Daily Telegraph* that the latest figures issued by the German Statistical Office show that the post-war marriage boom is even more accentuated in that country than in England and Wales. In the March quarter of 1920 the rate in the new Germany reached the unprecedented figure of 25.80 per 1,000 of the population, nearly double the rate for the corresponding quarter of 1913. In England and Wales the March quarter has long been the one in which fewest marriages are solemnized, but while those of 1914 were 11.2 per 1,000, the figure for 1920 was 14.8. Like those in England,

the German marriages show a great rise in the proportion of widows remarrying. In Bavaria, before the war, only 6.9 per cent. of the women marrying were widows, while in 1919 the number had risen to 13.8 per cent. There is, too, an increase in the ages of the contracting parties. Before the war only 20 per cent. of the men marrying in Herse were over 30 years of age, while in 1919 the percentage had risen to 32. In 1913 36 per cent. of the women were over 25 years of age; in 1919 the percentage was as high as 51.

State Medical Benefits.—Dr. Addison received at the Ministry of Health on February 10 last a deputation from the Trade Union Congress, which was then in session, who submitted a series of resolutions passed by the Congress relating to national insurance, the provision of a State medical service and the treatment of patients by panel doctors. The points urged by the deputation were: (1) Payment of increased benefits under the Insurance Acts for sickness of £1 a week for twenty-six weeks, and 10 shillings for the remainder of disablement; all members of 70 years of age, and becoming uninsurable, to receive 10 shillings a week disablement pay for the remainder of life. (2) The institution of a full medical service throughout the Kingdom under the Ministry of Health, the present hospitals and infirmaries to be taken over for the purpose and moneys provided by Parliament and local authorities. (3) An inquiry into the treatment of patients by panel doctors and a suggested limitation of the number of patients taken by one doctor. (4) Unhealthy and dangerous occupations to be provided for by State liability. Dr. Addison, in reply, said that while he was sympathetic to some extent with the aims of the deputation, they were asking the department to incur expenses which in the present condition of affairs it could not afford. The increase in the benefits under the Insurance Act, was not a practical proposition, nor was the suggested allowance of 10 shillings a week disablement pay to uninsurable persons of 70 years of age, which would involve an additional expenditure of forty million pounds a year. With regard to panel patients, the department had already limited their number to each doctor, and where the cases were more than the doctor could properly deal with the obligation rested upon him to employ an assistant. As for the provision of a State medical service, the time was not opportune for the consideration of such a proposal.

London Recuperative Homes for the Victims of Shell Shock.—The Ex-Service Welfare Society was formed with the object of securing for ex-service men of all ranks suffering from nervous and mental breakdown the best possible conditions for their recovery. The society takes the view that such cases are quite inadequately dealt with in asylums and that what is required is the proper atmosphere of cure and treatment of the most intensive kind. A recuperative hostel, or home of recovery, has therefore been started at Hampstead and another is to be opened shortly at Putney. Dr. Davis Waite and Dr. Laughton Scott have given recently some interesting particulars of the objects in view. The homes are to suggest a country house rather than a hospital. They

will be comfortably furnished, and each patient will be treated, as far as possible, as if he were in his own house. In the decoration of the house attention will be paid to the color scheme, which has been found of definite remedial value. The homes will be fully equipped for those forms of treatment which are found of great benefit at European and British Spas, among which are electrical baths, sedative baths, and lavage. Particular care is directed to dietetic treatment. The matrons and nurses have been selected for their proved skill and enthusiasm, and the services of expert medical advisers will enable each patient to enjoy the fullest benefit from modern psychotherapeutic methods.

The Expenditure of the Ministry of Health.—

A great deal of criticism is being launched by a section of the lay press against the schemes formulated by the Ministry of Health and in connection with the Ministry of Health stringent strictures have been made by certain journals which have a large circulation and consequently carry a considerable amount of weight, with respect to records which have been ordered by the National Health Insurance authorities to be kept by panel doctors of their patients. These records are to some extent public and a great fuss has been made in these journals as to the offence against recognized medical ethics in divulging professional secrets. These statements are exaggerated and that this is the case is evident from, at any rate, the fact that the two principal medical journals here have made but slight reference to the subject and have forbore to criticize. This attitude is doubtless because nothing is found to criticize with regard to record keeping. The nation is growing under taxation, and capital is made out of this by prejudiced journals to attempt to discredit the government. The Health Department is, perhaps, the one which has laid itself most open to criticism, mainly, perhaps, on account of its housing bill, and therefore every step taken by this department is subjected to almost virulent and oftentimes unfair criticism. It must be borne in mind that the keeping of records is essential to progress in medicine and surgery witness the success of "follow-up" departments in some American hospitals. In the leading article of the *Lancet*, February 12, comments are made upon an article by Dr. C. L. Gibson, which appeared in the *Annals of Surgery*, December, 1919, and which is an analysis of the results of six years' follow-up system in a hospital surgical service. The system is successful in that as the *Lancet* says it is only by such records of past history and happenings that real progress can be made in medical or surgical treatment, and it is to be hoped that establishments of this sort will rapidly be founded in all big hospitals. The animadversions against the policy of the Ministry of Health have been so acute that Dr. Addison, the Minister of Health, has thought fit to defend the schemes and doings of his department in the public press. In the course of his article he points out that some of the critics seem to be under the impression that the financial burdens of the Budget are at all events in a great measure due to the Ministry of Health and fail entirely to

realize how small a proportion fall on our national expenditure. On November 30 the Budget estimate for the year 1920-21 was stated to be £1,423,600,000. Of this prodigious and alarming sum only £1,100,000 was required in respect of maternity and child welfare services for England and Wales. This represents somewhat less than one-fifth of a penny (two cents) of each pound in the Budget, so that if the most enthusiastic reactionary had his way and the whole service were wiped out, including not only those developments of it for which the Ministry of Health is responsible, but the whole service lock stock and barrel, the relief to the taxpayer would be one-fifth of a penny out of every pound of taxation. He goes on to state that the particular services that the Health Department have sought to develop are: The health of the mother during and after confinement, and secondly, the welfare of the infant and little child. The maternal mortality due to childbirth is still high. From four to five mothers die per 1,000 children born and many more are injured permanently or temporarily. There is thus a loss to the nation of about 3,500 young women every year, a loss which should largely be prevented and which the department aims at reducing as much as possible. The Ministry are trying to do this by supervising the health of the expectant mother, by improving the midwifery service, and by providing small maternity homes where women whose home conditions are unsatisfactory, can be attended at childbirth under cleanly conditions by skilled workers. The department rely on two chief methods for promoting the welfare of the little child, namely, health visiting and the development of infant welfare centers. The object of both is education, the health visitor advises and teaches the mother in her own home. At the center the mother is advised by the doctor how to bring up her baby and how to keep it in good health. The intention is to train the mother to keep the baby well and prevent it from falling sick. During the past few years there has been a substantial increase in the number of maternity and child welfare centers, especially in the industrial districts where they were sorely needed. Dr. Addison said he had noticed that some of the department's hostile critics showed a really extraordinary promptitude to suggest that although this most remarkable decline in the infant death rate had occurred during the past two years, the Ministry of Health could not in any way claim any share in having assisted toward this result. Dr. Addison remarks that far be it from him to put forward high claims, but there is an almost ostentatious unfairness in criticism of this sort. It is pointed out that the awakening which the war has caused as to the vital necessity for the preservation and care of the childlife of the nation is a most important contributory factor. Increased wages and better feeding of the mothers are others. To pretend, however, that the improved measure of cooperation and effort in all directions of the local authorities and voluntary agencies which have been encouraged by the Ministry of Health and the sustained efforts which all have made to improve the quality of the service available have not had an

important share in producing the improved result is to ignore the true facts of the situation. The Ministry of Health have their hands too full and the housing scheme on account of its cost has rendered the department somewhat unpopular, but at the same time much of the criticism directed against its policy is far fetched and unjust.

4. Defective Delinquents in the Army of Occupation. L. Vernon Briggs.

2. **Primary Disease of the Pelvic Lymphatic Glands. An Unrecognized Gynecological Condition.**—John T. Williams presents the histories of three cases which lead him to the conclusion that primary enlargement of the pelvic lymph glands is a distinct clinical entity not generally recognized in gynecology. The diagnosis is to be based upon a pelvic mass definitely not connected with the uterus or its appendages, giving rise to pain and tenderness referred to the iliac fossa of the affected side, with or without elevation of temperature, and with or without psos spasm on the affected side. The white count in the cases observed has been only slightly elevated. The treatment of the disease of the pelvic lymph glands is the same as that of enlarged or diseased glands elsewhere in the body. A mass definitely containing pus should be opened. Where the glands are acutely inflamed, but suppuration has not taken place, treatment should be restricted to rest and cold applications. Where enlargement of the glands is sufficient to cause pressure on important organs and does not rapidly subside under palliative treatment, excision is indicated.

3. **Indirect Expulsion of the Placenta.**—Joseph L. Baer describes as follows a procedure which he considers a reversion to nature's spontaneous method, utilizing the full power of the abdominal muscles to drive the uterus down against the separated placenta and so expel it. After the usual period of waiting, averaging half an hour, the placenta being separated, the uterus being in the midline and at the height of a contraction, as evidenced by its hardness and the pain the woman is experiencing, the abdominal wall is grasped by one or two hands, crosswise above the umbilicus, the fingers on one side beyond the rectus, and the thumbs on the opposite side also beyond the rectus. The recti are then pulled together and held firmly, thus taking up all the slack in the relaxed overstretched wall. The woman is now urged to bear down exactly as in the second stage of labor. Cooperation is essential, but

need last only a moment, the placenta being expelled exactly as in the spontaneous cases. Successful co-operation can be told by the tensing of the recti and their tendency to pull apart. The correct grip prevents this and the force is properly transmitted, that is, against the uterus. The method is applicable only after separation has occurred. This method was 90 per cent. efficient in the hands of seventeen men of limited experience. It entirely avoids manipulation of the uterus, and is considered worthy of a fair trial and possibly adoption as a routine.

5. **Angina Pectoris of Diabetes.**—Max Kahn considers that in treating a diabetic patient complaining of cardiac distress, the physician should make a thorough examination of the heart, and should determine whether or not the case is complicated by renal disease, and should prescribe the rest and quiet so essential in its relief, besides using the various medicinal remedies in his armamentarium, as well as controlling the diet. The bromides and codeine may be used as a sedative. One should particularly remember the fact that diabetes is essentially a disease of low blood pressure and one should not, on hearsay, prescribe the various drugs that induce reduction of blood pressure in his attempt to ameliorate the pain of angina pectoris.

7. **Juvenile Tabes.**—Charles Rosenheck reports a typical case of this rare condition, and from his study of the subject draws the following conclusions: 1. Juvenile tabes may be considered a distinct clinical entity in view of the long accepted dictum that adults alone were subject to the disease. That the creation of separate entities in a disease that affects both young and old may be justly criticised as being clinically confusing and scientifically unsound is not denied; but in view of the rarity of its occurrence and the special characteristics of the affection in the young, juvenile tabes is deserving of special recognition. 2. Juvenile tabes is the result of an hereditary syphilitic infection in the great majority of cases. An insignificant number of cases are due to syphilis acquired during infancy. 3. Its symptomatology differs in no way from that of the adult type, but special characteristics in its onset and course are worthy of note. 4. Early visual difficulties proceeding to blindness and optic atrophy are characteristic of fully 40 per cent. of the cases. 5. Lancing pains, ataxia, and visceral or vesical disturbances affect only a small number. 6. Trophic disorders are absent. 7. Females are particularly vulnerable to the affection; as twice as many girls show the disease as boys. The ratio in the adult type is placed as ten men to one woman (Gowers). 8. The prognosis is excellent for life, but extremely poor for vision.

2. **An Investigation of the Cause and Relief of Pain in Gastric Ulcer.**—E. P. Poulton shows that an important element in the pain of gastric ulcer is due to distention of the stomach, and that it can be abolished by reducing the intragastric pressure. Two methods were adopted in this investigation: 1. A fine rubber tube similar to that used for withdrawing stomach contents in the fractional test meal method is passed into the stomach. There is some lead in the lower end of the tube, so that it can be localized by means of x-rays. Air or oxygen is passed into the stomach through the tube from a reservoir connected with a water manometer, so that the pressure exerted by the air current can be measured. The patient is asked to describe his sensations, whether of fullness or pain, while his stomach is being distended. 2. The patient is asked to pass a similar tube into the stomach when pain is experienced, and in many cases the pain is relieved within a few minutes by release of pressure. The tube should contain a

series of holes extending from its end in the stomach upward as far as the cardiac orifice. Stomach contents may be regurgitated through the tube. The gastroduodenal tube is a modification of the gastric tube. It connects the stomach with the duodenum, so that pressure is equalized through the pylorus. It is about two feet long, and contains holes about $1\frac{1}{2}$ inches apart throughout its length. Both ends are made opaque to x-rays by means of short pieces of thick lead fuse wire placed inside the tube between glass beads (in order to keep the digestive juices away from the lead) and securely fastened with silk. To one end of the tube is attached a piece of silk about 27 inches long. The end of the tube not attached to the silk is passed into the stomach, and then usually passes quite readily through the pylorus. The upper end of the tube is then anchored in the stomach 22 inches from the lips by means of the silk, which can be fastened round the ear or round a dental plate or pinned on the dress. The position of the tube can easily be determined by skiagraphic examination after the stomach has been outlined with a little barium sulphate suspension. It is important not to pass this tube too quickly into the stomach, for if the proximal end reaches the stomach before the distal end has reached the pylorus the tube may become tied into a knot and fail to get through at all. Thicker walled tubing is preferred to the thin rubber tubing, which is easily acted upon by the digestive juices.

5. The Operative Treatment of Prolapse (Procidentia) of the Rectum in Adults.—J. P. Lockhart-Mummery gives the following technique, to be performed after proper preliminary treatment: The rectum is thoroughly cleaned out with ether soap and lysol solution, and finally with 75 per cent. spirit and picric acid, the skin of the perineum and buttock being similarly rendered aseptic; after the prolapse has been returned a piece of gauze is placed in the rectum to prevent leakage during the operation. A transverse incision is next made about $2\frac{1}{2}$ inches long midway between the tip of the coccyx and the posterior margin of the anus. This is deepened until the connective tissue between the rectum and the sacrum is opened. With blunt dissection or with gloved fingers this space is opened as high up as possible and laterally till the rectum has been freed thoroughly at the back and sides. The whole of the space thus opened up is now lightly packed with sterilized vaseline gauze two inches wide, and made with a sewn edge, so that it will not fray and leave particles behind. A very considerable amount of gauze tape is used, but the object is to get this spread as flat as possible and not merely to fill the pelvis with it, and so block the rectum. As much as 40 yards of gauze have been employed in some cases. The end of the gauze is left protruding from the wound, and if (as is usually the case) more than one piece is used all the ends are firmly tied together at the finish. The anus is then restored. The type of operation for this purpose varies according to the condition to be dealt with. The method usually employed by the writer is to extend the ends of the previous incision forward on each side to about half-way between the anterior and posterior margins of the anal orifice. The flap thus formed is dissected up so as to expose the posterior half of the external sphincter. This muscle is then carefully defined and the lateral portions sewn together from behind forwards until the anal orifice is narrowed to the extent considered desirable. No. 1 catgut is used for the stitches, and they are not pulled tight enough to cut through the muscle fibers, but just to bring the sides of the sphincter in close contact. Supporting sutures are put in, and then the flap is loosely stitched back in position, leaving room for the removal of the gauze packing later. A short tube is placed in the rectum to prevent prolapse should the patient strain coming round from the anesthetic, and the whole perineum is covered with sterilized dressings. The wound is dressed twice daily and fresh dressings applied, but the packing is not removed for a week. An anesthetic is then given, all the packing removed, and a fresh lot of gauze introduced. This is left in for five days or a week, and then removed, no fresh gauze being introduced at this time, a drainage tube being placed in the cavity left by its removal. The wound should not be allowed to heal under three weeks, the more slowly

it heals the better being the results. The bowels are kept confined until the seventh day after operation, when they are relieved by an enema before the removal of the packing; after this they are opened daily with an enema. The patient is not allowed out of bed for six weeks and not allowed to sit up for an action of the bowels for two months at least. The prevention of sepsis is most important.

4. Treatment of Gonorrhea in Women.—Remington Hobbs discusses this subject with special reference to cases complicating pregnancy. It is generally held that treatment of the cervix is contraindicated, in cases of gonorrhea complicating pregnancy, by the risk of miscarriage, unless the circumstances are very exceptional, and the writer is of the opinion that under improper or unsuitable treatment this risk is a real one. He holds that there is greater risk of miscarriage from the infection of the endometrium than from properly applied treatment to the cervix. It is not only safe to treat the cervical canal, but decidedly in the patient's interest to do so. The eradication of the disease from the cervix presents one of the main difficulties, for by reason of the burrowing tendency of the gonococcus the deep-seated glands become infected, which after a time occludes their lining by adhesions. Gradual distention of the glands ensues, and ultimately the formation of small abscesses. In order to render the ducts patent again, it is necessary to denude a thick layer of epithelium, so that treatment can be more directly applied to the deeper structures. All that is necessary can be done to the endometrium with a minimized dilatation, irrespective of the condition of the surrounding adnexa, provided there are no acute symptoms. This simple operation can be repeated until the uterus is firm and hard, and the secretion in the cervix is normal. This method of treating the endometrium lessens the amount of congestion in the surrounding tissues, and does not promote it. From a surgical point of view cases are very familiar in which the tubes have been removed and the patient is as bad as ever, owing to the infection of the endometrium and cervix. When the infection is of an ascending type and salpingectomy would be necessary if other measures failed, the treatment outlined, unless the inflammation be of the grossest kind, obviates the necessity for surgical interference. An intensive form of treatment, as indicated, can be undertaken in cases of chronic gonorrhea, even in pregnant women, and it will do much to ameliorate the gravity of the conditions and to shorten the course of treatment.

4. A Study of the Pneumococcus and Streptococcus Groups in Their Relation to Influenza.—W. R. Logan studied the pneumococci and streptococci from cases of epidemic influenza, first in their relation to the earliest

stage of illness, when the infection was presumably a comparatively pure one; and second, with regard to their part in the more advanced cases, when pulmonary complications had set in. It was shown that pneumococci and aerobic streptococci could be cleared of suspicion of acting as initiating organismal causes in the epidemics; that the pathogenic organisms of these groups which were associated with the production of pulmonary complications were of a variety of types; that many of these were definitely infections from without, while with the remainder limitations of technique prevented exact proof as to their origin being brought forward; that the presence of saprophytic streptococci and of presumably saprophytic pneumococci in the lungs of many advanced cases may be explained as a late invasion of the already diseased lung, either by the patient's own mouth organisms or by the saprophytic mouth organisms passed on from another patient, while their presence in the sputum is, in many cases, due simply to the contamination of the specimen with organisms from throat and mouth. Both from the point of view of the history of the individual case and from that of the history of the epidemic itself, one may divide influenza into three stages: a primary stage, when the unknown infecting virus, whether it be Pfeiffer's bacillus, or some other organism, is apparently acting alone, though presumably frequently accompanied by other organisms which may or may not later be able to develop a like activity; a secondary stage, when pathogenic pneumococci and streptococci are active in producing pulmonary complications, either alone or along with other pathogenic organisms; and a tertiary stage, when saprophytic mouth organisms may invade the already diseased lung. It was shown that the type of pulmonary complication is to a considerable extent dependent on the type of pathogenic pneumococcus or streptococcus present; that pneumococci of Types I, II, and III, were associated, as was to be expected, with pneumonias showing definite consolidation, as were also certain of the Group IV pneumococci; that others of the Group IV pneumococci and the hemolytic streptococci were associated with complications of the bronchopneumonic and bronchitic types. The presence of complex infections in epidemics of this kind does not imply that the original bacterial cause at the beginning of the outbreak was not a single type of microorganism; nor does proof that the important organismal varieties are always types foreign to normal mouths and throats—are, in fact, infections from without—imply that the real primary agent in such epidemics may not be a temporary susceptibility, individual or general, due to causes at present unknown.

Implantation of the Sexual Glands.—Lydston, of Chicago contributes an original article on this subject and complains that he has been ignored by both Voronoff and Steinhach. His own début in the literature of this subject goes back to 1914. In one influential journal alone he published during that year no less than seven communications, and it is difficult to comprehend how his priority could have been ignored in Europe. The author then abandons the question of credit due and sums up the results of his extensive experiences, including one personal one. The recipient of the graft obtains a certain amount of hormone from the gland itself. Then the implanted interstitial cells of Ludwig continue to produce hormone for a longer or shorter time or until the implant has been absorbed or has come away. But the recipient obtains something in addition to the hormone, and this is probably an enzyme or other principle which acts as a stimulant to the entire organism. In other words, the hormone which produces the return of sexual potency may be distinct from that which generally stimulates the organism. In regard to human donors the glands may be derived from the victims of accident, acute poisoning, the drowned, gas-intoxicated, and those killed by hanging (but not the electrocuted). The criterion is instantaneous death, but this point could be stretched a little to include those who survive for a few hours (acute

intoxications). The results in practice differ greatly with the type of patient, the age, lack of masculinity, kind of impotence, etc. The most remarkable result cited was in a youngish man who was markedly effeminate, but apparently not an invert, who underwent a complete change of personality after one act of implantation.

3. Smallpox and Vaccination Lantern Slide Lecture. F. E. Stewart.
4. A Few Words upon the Subject of Divine Healing and Something in Reference to a Cult That is Neither Christian Nor Science. Rev. Everett G. Johnson.

1. Pain in Diseases of Abdominal Viscera.—W. H. Foreman, in this, the first of a series of papers which will deal with gastrointestinal conditions, emphasizes the following points: 1. Visceral pain, due to distention, which the mind has learned to locate in the average position of the organ. 2. Referred pain which is the result of the arrival in the spinal cord of impulses from the diseased viscera, referred to the periphery of the sensory spinal nerves which arise from the spinal segment to which the visceral afferent nerves pass. 3. Parietal subperitoneal pain due to extension of the inflammation to the adjacent parietal subserous tissue. 4. Afferent sympathetic nerve fibres convey the visceral stimuli adequate to produce visceral or referred somatic pain. 5. Sensory spinal nerve fibres only are concerned in parietal subperitoneal pain.

II Policlinico.

January 24, 1921, xxviii, 4.

Epidemic Hiccough.—Zuccola of Cuneo refers to a type of what he calls epidemic encephalitis which seems to be distinct from the prevalent form. The first cases were reported from certain parts of France, and now something of the kind is evident in Italy. Unlike the older disease, the course is mild and the inception insidious. There is slight malaise, the head feels heavy and there is a certain amount of headache and vague rheumatoid pains in the body at large. The digestive and respiratory systems are almost spared. Fever may be slight and even absent, and chilliness is more marked. There are no pareses of the ocular muscles or implication of cranial nerves. Seemingly the chief if not the sole symptom is a clonus of the diaphragm, 15 to 25 to the minute, which may or may not be simple hiccough. It is not influenced by anything in the way of posture, medicines, etc. The condition is certainly not new in medical literature and the author cites many Italians who have formerly reported such cases. Hiccough has also been seen in both encephalitis lethargica and influenza, but the author believes in the autonomy of the new affection.

Incontinence of the Pylorus.—This is one of the new radioscopic maladies which has of late been attracting attention. At a session of the Paris Surgical Society last fall, reported in *Le Progrès Médical* for January 1, 1921, xlix, 1, Aubourg showed his fourth case. The prerequisite for its development is absence of all contraction of the stomach which involves failure of the pylorus to close. The ingesta pass directly into the duodenum on reaching the stomach. Other factors are tumors involving the pyloric sphincter and affections of the vagus and its gastric ramifications. There is no semiology of this condition, but under radioscopy we note an absence of contractions of the stomach and a gaping pylorus. The chief significance of the phenomenon is the revelation of the importance of the vagus to the gastric functioning. It is possible to divide affections of the organ into two groups in which there is either increased or defective innervation. In resection of the stomach involving the lesser curvature the terminal filaments of the vagus are apt to be sacrificed. The prompt escape into the intestine of undigested food naturally causes further trouble; one recent writer has noted the presence in these cases of fecal accumulations.

Book Reviews.

DIAGNOSTIK UND THERAPIE DER KINDERKRANKHEITEN. Mit speziellen Arzneiverordnungen für den praktischen Arzt. Von Prof. Dr. F. LUST, Oberarzt der Universitäts-Kinderklinik in Heidelberg. Zweite neubearbeitete Auflage. Berlin und Vienna: Urban & Schwarzenberg, 1920.

The first edition of this book appeared in 1918, the second in 1920. It is rare to see a text-book on the Diseases of Infancy and Childhood without illustrations. This book has been used by the students of the Heidelberg University and is intended to give the symptoms, the diagnosis, the differential diagnosis, and the treatment of infantile diseases. It does not describe the bacteriology or the pathology of diseases, but leaves these to other works dealing with these special subjects. The book is intended as an up-to-date handbook on diagnosis and therapeutics.

A TEXTBOOK OF MATERIA MEDICA. Being an Account of the More Important Crude Drugs of Vegetable and Animal Origin. Designed for Students of Pharmacy and Medicine. By HENRY G. GREENISH, F.I.C., F.L.S. Professor of Pharmacotics in the University of London, Director of the Pharmacy Research Laboratory, etc. Third edition, London: J. & A. Churchill, 1920.

The first edition of this book appeared in 1899 and the second ten years later. In the present edition the size of the book has been reduced while at the same time there have been numerous additions. The animal products now number 12, as follows: the leech, Spanish flies, cochineal, suprarenal and thyroid glands and pancreas, ox gall, pepsin, gelatin, musk, castor and cuttle fish bone. While the parathyroids, hypophysis, spleen, and thymus are mentioned they are not formally described. The book is considerably richer in information concerning the vegetable materia medica of the British Pharmacopoeia. Thus scammony appears under two classifications, gum-resins and roots, making nearly four pages of pure materia medica; while in the Pharmacopoeia the space devoted to the same subject is much less. Pyrethrum is described in two classifications, flowers and root, with double the amount of space found in the Pharmacopoeia, where flowers and root are described together.

MALARIA AT HOME AND ABROAD. By S. P. JAMES, M.D., D.P.H. (Lieut.-Colonel, I.M.S., retired). Fellow of the Society of Tropical Medicine and Hygiene, Fellow of the Royal Geographical Society and the Royal Society of Medicine, etc. New York: William Wood & Co., 1920.

The 10 sections of this volume are devoted respectively to the parasitism of the mosquito as the cause of the disease, which requires 4 of the sections; malarial surveys of England and of the tropics (two sections); the symptomatology, pathology, and diagnosis of malaria in 4 subsections; treatment of malaria; prevention and eradication of the disease and mosquito control. There are over 100 full page and text figures to 234 pages of text. The recent date of the book, together with the large number of illustrations, tend to give it precedence over other works in English. While the text is not voluminous in comparison with such great productions as the Italian work of Ascoli, there is a very full consideration of all the essentials of malaria and the book is entirely practical in its scope.

THE SERBIAN EPIDEMICS OF TYPHUS AND RELAPSING FEVER IN 1915, ETC. By WILLIAM HUNTER, C.B., Colonel A.M.S. Reprinted from the Proceedings of the Royal Society of Medicine, 1919, Vol. XIII (Section of Epidemiology and State Medicine), pp. 29-158. London: John Bale, Sons & Danielsson, Ltd., 1920.

Of three parts comprising the volume, the first shows the conditions preceding and present on the arrival of the Sanitary Mission, and the measures introduced by the latter. Part II describes the campaign against the disease until the latter was arrested and brought partly under control while Part III gives the status at the time of writing. At that juncture the work was by no means complete. The quarantine and cleansing station was firmly established with disinfection and

inoculation measures. The number of cases of typhus had been reduced one-half and of relapsing fever three-fourths, while typhoid had nearly been stamped out and over 20,000 men had been immunized against cholera.

THE COMMUNITY HEALTH PROBLEM. By ATHEL CAMPBELL BURNHAM, M.D., Health Service, Atlantic Division, American Red Cross; Attending Surgeon, Volunteer Hospital, New York City; Lieutenant-Colonel, Medical Reserve Corps, U. S. Army; Fellow New York Academy of Medicine. New York: The Macmillan Company, 1920.

THIS book may be divided into two parts. In the first part there appears an economic discussion which focuses the attention on the extent of sickness, gained from sources such as disability discovered by the draft, sickness surveys, examinations of school children, community health surveys, Framingham Health Demonstration and the Rockefeller Foundation. From these sources it is shown that "non-effectives" due to sickness at all times constitute a large group and reflect an economic loss to the community; from which it is justly premised that the public health problem of today not alone affects the individual but is a matter also for community consideration.

Following this the remainder of the book is devoted to a discussion of community activities in securing public health. There are discussed the campaign for better health, workmen's compensation and insurance, and compulsory insurance, these representing the combined efforts of the lay and professional campaigns. Then the purely professional activities, including industrial medicine, State medicine, and health centers, are presented. Chapters are included on special topics such as the social unit experiment and the question of tuberculosis. The obligation of the public in the matter of rehabilitating the disabled soldier is mentioned, though rather too lightly than too forcibly.

In its entirety the book represents a good elementary treatise that furnishes in a small compass a comprehensive understanding of the relation of social medicine to community health.

ANNALS OF ROENTGENOLOGY. A Series of Monographic Atlases. Edited by JAMES T. CASE, M.D., President of the American Roentgen Ray Society. Volume 1, "MASTOIDS ROENTGENOLOGICALLY CONSIDERED." By FREDERICK M. LAW, M.D. New York: Paul B. Hoeber.

DOCTOR LAW presents the classification of mastoids based on two general types: the non-cellular, including undeveloped or infantile, diploetic, and sclerotic; and the pneumatic, including large cell, small cell, and mixed type. Each sub-type is described and a table presented of the important points to be taken into consideration in the roentgen-ray examination of the mastoids.

Under the heading "The Pathological Mastoid" the course of the inflammatory phenomenon is reviewed and a summary given of the conditions definitely revealed by shadows on the plate. These are, 1, hyperemia of the mastoid cells; 2, mild acute mastoiditis; 3, purulent mastoiditis; 4, softening of the cell walls; 5, necrosis of the cell walls; 6, exposure of the sinus groove; 7, exposure of the dura; 8, cholesteatoma; and 9, sclerosis. Each condition is discussed and the points of x-ray importance that make for correct interpretation are emphasized. Some important features incident to the general technique are found in the descriptive section of the Atlas, and include a discussion of the posturing, the factors of exposure, and the photographic developing of the plate. There follow twenty-one exceptional prints illustrating pathological mastoids, their interpretation being furnished in the English, French, and Spanish languages.

The Atlas is remarkable for the clearness of descriptive exposition, for the artful skillfulness in the reproduction of the prints, and for the lucidly comprehensive interpretations supplied. Dr. Case, in the editorial preface to the volume, states that the Annals are meant to supply a series of "master roentgenograms that the roentgenologist may study at will." From the success manifestly achieved in this volume, there can be no doubt that "master roentgenograms" and "master interpretations" have been supplied.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting Held January 6, 1921.

FIRST VICE-PRESIDENT DR. CHARLES H. PECK IN THE CHAIR.

THE program of the evening was arranged by the Society for Experimental Biology and Medicine in association with the Harvey Society as a memorial to Dr. Samuel James Meltzer.

At a brief executive session the annual reports of the officers of the Academy were presented by title and accepted, and a resolution was passed increasing the resident membership of the Academy from 1300 to 1350.

Dr. PECK stated that the meeting had been called in memory of Dr. Samuel James Meltzer, a scientist of international reputation and fame, and one of whom the New York medical profession was justly proud. It was fitting that the president of the society which Dr. Meltzer had founded should preside at this meeting, and he therefore invited Dr. Gary N. Calkins, president of the Society for Experimental Biology and Medicine, to take the chair.

Dr. GARY N. CALKINS related how in 1903 a small body of men met at Dr. Meltzer's invitation to talk over the organization of a society to discuss experimental medicine and the biological sciences. One month later the society was launched with nineteen charter members, and Dr. Meltzer as first president. One of Dr. Meltzer's outstanding characteristics was his interest in younger men and their progress in science. He saw in the National Academy a meeting place for those who had reached established heights in research and he liked to think of the Society for Experimental Biology and Medicine as affording a place for fledglings, the younger men, to try their wings. Dr. Meltzer was always a man of the highest ideals in research, and he followed up and nourished this society to see that the high ideals set before it were attained. They were glad to believe that the scientific spirit which he had fostered had extended to its entire membership of four hundred workers, and it was in recognition of this scientific spirit and out of respect to Dr. Meltzer that he asked those members and all present who felt as they did to rise.

Dr. GEORGE B. WALLACE sketched in a general way the characteristics and attributes of Dr. Meltzer which had impressed him most. He described his first visit to Dr. Meltzer, nearly twenty years ago, when Dr. Meltzer was fifty-one years of age. The conversation was concerning practice, but mostly research work. At that time he was impressed by the clearness, fairness, and enthusiasm with which Dr. Meltzer dwelt upon the scientific work being done in New York. He regretted that the men in this work did not meet to exchange views and he drew outline plans for a society for the discussion of the medical and biological sciences. The next year the Society for Experimental Biology and Medicine was formed. The last time he saw Dr. Meltzer was in New Haven last summer, when he was seventy years of age, and in miserable health. The journey was tiresome for him, and he told of a very bad attack from which he had suffered the previous night. He did not dwell long upon it, but went on to describe the excellencies of the meeting and the fine research work being done in this country. One felt the spirit that led him to endeavor to overcome his physical infirmities, and his love and appreciation of knowledge for its own sake.

In Berlin it was the study of philosophy that interested him most, and he probably would have pursued that line had not financial considerations led him into the study of medicine. The great teachers of medicine of that period, Kronecker, Ringer, and others, also attracted him to this field. After careful deliberation he chose to come to this country because its democratic form of government appealed to him. Before locating permanently in New York he was a ship's surgeon for a number of trips, though he was never a good sailor. He was a man impressed with the necessity for careful observation, and with the importance of facts rather than theories. In the course of some of his experi-

mental work in Berlin on the deglutition reflexes, an investigation was carried out which required the subject to sit for hours with two stomach tubes inserted into the esophagus. Dr. Meltzer became the subject of this investigation, and while in this position a Prussian inspector of an antivivisection organization visited the laboratory. These antivivisectionists had held that investigators inflicted suffering upon animals that they would not endure themselves. After seeing Dr. Meltzer they said they would not go through the suffering and discomfort which they had seen this student of physiology endure. It was needless to say that in that campaign the antivivisectionists lost the day. It was in these investigations in Berlin that the idea was brought out upon which much of his future work on inhibition was founded. His studies in inhibition led to those on magnesium sulphate which were so well known that they needed no review. The wide knowledge he gained from experimental work regarding magnesium sulphate he endeavored to use for the relief of suffering. The experimental work on magnesium sulphate led him on to the work on intratracheal insufflation for the maintenance of artificial respiration and the administration of anesthetics. This method was remarkable for its simplicity. Dr. Meltzer showed a breadth of view and a reach of subjects that was remarkable, as his many clinical papers bore witness. These papers all showed great powers of observation and careful interpretation of facts. His first publication was on the reflexes of deglutition. Another early publication was on the "Behavior of Red Blood Corpuscles" a piece of work done in association with Dr. Welch. These papers were the forerunners of others on physiological subjects and set the standards for American experimental work. Another side of Dr. Meltzer was his chastened and hesitating attitude toward medical research; his high altruism and good judgment kept him from being impractical. Dr. Wallace quoted passages from several of Dr. Meltzer's presidential addresses showing this attitude. In one of these he said the physician of the future would be the man who spent years in acquiring knowledge in the pure medical sciences; clinical medicine and the sciences must be brought together. He had a part in the organization of the Society for the Advancement of Clinical Research, a society which was unique in character, in the ability of its members, and in the excellence of their work. His address on "Clinical Medicine" was especially inspiring. Another on the "Organization of Clinical Departments" was very instructive. Through all his addresses one found proof of his faith in the future of medicine in this country. Dr. Victor C. Vaughan had written a letter which reflected the general regard in which Dr. Meltzer was held and the recognition that though a busy practitioner of medicine he always found time to do research work. To present a paper which called forth constructive criticism, or excited comment from Dr. Meltzer was to receive stimulation and guidance. A large group of young men looked upon him as a trusted friend and adviser, and a source of inspiration.

Dr. PHOEBUS A. LEVENE said he was here not to speak to the old friends of Dr. Meltzer, who with him led the medical profession through the thorny walks of the primitive lowlands of medicine to its present heights of perfection. He would not review all these memories but would say something to the younger members of the profession who were unacquainted with Dr. Meltzer in order to give a general impression of his character, and one that the younger man might hold before himself while his life and ideals were in the shaping. He would picture him as a man expressing the great idea of service to humanity. It happened that Dr. Meltzer was born in that great country of irrepressible idealism, Russia, and it so happened that he was born of a race noted for its devotion to that which it chose as the object of its devotion. He was born in the modest city of Courland, not noted for its bankers and financiers, but where learning was held in great love and veneration. In the search for learning he dropped his native land and went to Berlin, and there came to know the great men of literature, philosophy, and medicine, and medicine became the medium of his service toward humanity. Physiology became the medium of his service to medicine and of his perfection. So thoroughly did he apply himself to the mastery of this

medium that his teachers became his friends and comrades, and had he remained in Germany opportunity was offered him to become one of them. But considerations already pointed out or perhaps an **impelling desire** for broader activities caused him again to emigrate, this time to our land. Imagine the background he had in his masters in Berlin, the background of big institutions and big ideas; when he arrived in this country the comparison of the present with the past was anything but cheering. We had at that time medical schools, it was true, but of institutions of learning we had none. As to laboratories, the space they occupied was in the annual announcements of the colleges; on the premises one had to search for them, and after search not find them. With his advantages it would not have been difficult for him to have exploited himself as a physician for personal gain. Other men who came at the same time did exploit their advantages, but Dr. Meltzer did not. He imposed upon himself the task of educating and broadening the American physician. Others who had the advantages of education abroad took upon themselves the same task, notably, Dr. Welch, Dr. Prudden, Dr. Janeway, Dr. Knapp, and others, but among them the position of Dr. Meltzer was unique. To what was this due? To describe it in one word, he was more democratic. The other men devoted themselves to university medical schools or hospitals, while Dr. Meltzer preferred to be independent and to devote himself to the education of the rank and file of the profession, whether in academic work or in the practice of medicine. To borrow from the political vocabulary, he had initiated the progressive minority against the conservative majority. Though for many years he remained unaffiliated with medical schools or hospitals, he realized the necessity for participation in active research. Many of his contemporaries became leaders in hospitals and lost their habit of research, and over them he had a great advantage. In addition he had an insatiable desire for reading, and also the advantage of a phenomenal memory. So it happened that though unaffiliated with hospital or university he became a leader, a critic, a teacher, and was called upon to present every new idea in medicine that appeared in Europe to the American profession. The reason he was successful in presenting these new ideas was that he assimilated them and tried them out in his laboratory, where he toiled and labored to attain self-perfection, and through his self-perfection to aid his fellow men. While still in the full vigor of life he saw his aim accomplished. Medical research was reaching a stage of activity he never dreamed of. He then thought he could devote himself to matters nearest his heart—these were the problems of physiology, some old, some new, and it so happened that the Rockefeller Institute for Medical Research came into existence and the opportunity opened for Dr. Meltzer to do what he liked. What he accomplished there had already been told and the rest might be told by men more competent than the speaker. To him Dr. Meltzer's scientific work and attainments spoke second; his life spoke first. It was a simple life; simple in its dignity, in its honesty, in its purpose, and in its service. The record of his life was the message Dr. Meltzer left not only to his friends and colleagues, but not only to the medical profession, but to all.

Dr. WILLIAM H. HOWELL said he wished to speak of Dr. Meltzer's contributions to physiology from the time he came to New York in the early 80's, as a ship's surgeon, poor and unknown, to the time of his death, when he was known throughout the length and breadth of the land as a prolific investigator. He had published two hundred and forty or more papers in forty-eight scientific journals in this country, in England, and in Germany, on subjects pertaining to physiology, pharmacology, pathology, and clinical medicine. It was a remarkable tribute to the breadth of his thought that he was an accredited investigator in all four branches. He was a member of some twenty societies, including the most important in these fields, and in every one of them he was able to take his part as a contributor or in discussion of the papers. It was also noteworthy that he had been president of many of these societies, of the Association of American Physicians, American Physiological Society, Association of the Advancement of Clinical Research, and the Harvey Society. It

seemed unique that one individual should have had this recognition from specialists in so many different branches. While his contributions were on many different subjects his first love was physiology, and in that specialty he became recognized as one of the foremost of American physiologists. His first contribution appeared in the transactions of the Berlin Physiological Society in 1880. In this he stated that he had severed the nerve going to the myohyoid muscle, and had demonstrated the importance of that muscle in deglutition. To the physiology of deglutition this was an important contribution. It introduced a new theory of the physiology of swallowing which had come to be universally accepted. Soon after this appeared the paper on the "Irritation of the Swallowing Centers and Their Importance." This was noteworthy for two reasons: it presented the widespread effect on the nervous system of the act of swallowing, and it brought out Dr. Meltzer's idea of inhibition. After discussing this theory, Dr. Howell said that Dr. Meltzer had attempted to support it experimentally all his life. It was perhaps not possible to say anything of its correctness or incorrectness as we were still very uncertain as to what entered into inhibition, but it might be stated that Dr. Meltzer was far ahead of his contemporaries in his understanding of inhibition. To him the theory was a rewarding one, a sort of compass by which he recorded his experimental physiological voyages and which served to explain his work in the laboratory. Without it one could not appreciate his position on the subject of shock. Nine or ten of his papers were written in collaboration with his daughter, Mrs. Auer. Dr. Howell reviewed some of the more important points brought out by Dr. Meltzer's experiments on the effect of epinephrin on blood vessels, in that of magnesium sulphate on the nervous system, and the antagonistic effect of calcium chloride, and on intratracheal insufflation for the maintenance of artificial respiration and for the administration of anesthetics. It was very evident that the latter had a wide field of application. Time and again Dr. Meltzer had attempted to bring this method into practical use in surgery, and it had met with some recognition in thoracic surgery; the principle would be used more and more. This investigation into the methods of artificial respiration led him to take an interest in the matter of resuscitation after accidents of various kinds, such as industrial accidents and drowning. He wrote a paper showing that artificial respiration was the most effective method of resuscitation for both man and animals, but realized that it required some anatomical knowledge and skill in order to apply it. He then turned his attention to pharyngeal insufflation and devised an apparatus for pharyngeal insufflation which was simple and the best single method of artificial respiration. He demonstrated that it was more efficient than any of the so-called manual methods and better than the pulmotor and lung motor. It was a matter of record that he was not able to convince his colleagues that it met all the needs of industrial and drowning accidents. It required a little training in order to be able to use it efficiently, so they thought it would not be desirable to recommend it under ordinary conditions for artificial respiration. His contributions to the subject of artificial respiration would have an enduring value not only to surgery but on the industrial and military side. In addition to these lines of work Dr. Meltzer published papers on many topics which time did not permit him to refer to here. One of these, however, was a Harvey Society lecture entitled "Factors of Safety." He used this simple term to designate the reserve power of many physiological mechanisms. His idea had no doubt occurred to many individuals before, but it had not been so crystallized and brought to the attention of scientists. Instigated by Chittenden's work on low protein diets he undertook metabolic studies and investigated the relation of the pancreas to hyperglycemia and glycosuria, and the speaker was under the impression that time would show that Dr. Meltzer's views on this subject were correct. To do justice to his many contributions would require a careful review of almost all the medical literature of this period. It seemed that as an interpreter or a contributor he made a point of contact with almost all points of medical science and practice. No one in this generation had

done more to bring about a sympathetic understanding between the laboratory worker and the practitioner of medicine. As to his relation to the American Physiological Society, he was elected a member at its first annual meeting, in 1888, and he became its most faithful member in attendance, in making contributions and in discussion. Not only did he attend the meetings regularly, but he was a model in behavior. Many others succumbed to the load of papers and disappeared to get fresh air and relief, but this was never the case with Dr. Meltzer. He loved to listen to the papers and take part in the discussion, and scarcely a paper was read upon which he did not make some remarks which were stimulating and beneficial. His influence increased constantly. From 1911 to 1913 he was president, and both before and after that time his advice was dominant both on questions of science and on matters of policy. The American Physiological Society owed him a great debt of gratitude. Both in that society and in other societies, Dr. Howell said, he had been much impressed with Dr. Meltzer's courage in always speaking his mind. His frankness, simplicity, and courage in speaking what he believed to be the truth aroused admiration. Everyone recognized his sincerity and that personalities counted for nothing, that all his interest was in the subject. He had always found Dr. Meltzer high minded, sincere, simple, optimistic, and enthusiastic, and his enthusiasm did not cool with age. Advancing age made some men shrink from the routine of research work; he showed no sense of weariness, but was always full of zeal, hope, and determination to carry forward his ideals, and when death came it was while he was at work in his study, as he would have wished it. His colleagues loved to feel that he was a good and faithful servant of science and research. He had had his reward in fame and honors, but his greatest recompense, one loved to believe, came from the joy of work and, it was to be hoped, also from a realization of the affection and appreciation with which he was held by his scientific friends and coworkers.

Dr. GRAHAM LUSK spoke of his recollections of Dr. Meltzer's physiological work. He said that a constant attendant at every important meeting had passed from us in the fullness of years and in the honor and esteem of his fellowmen. He was deeply imbued with the spirit of modern German scientific medicine and a highly skilled practitioner. Dr. Meltzer was a man not content to carry on a lucrative practice at the expense of a curious mind. Dr. Lusk recalled that in 1897 he sat at a dinner of a few physiologists, between Dr. Meltzer and his (the speaker's) father, and his father had stated that he considered that his success in obstetrics was due to the fact that he was a trained physiologist, and a believer in contact with scientific men. Dr. Meltzer had a phenomenal knowledge of medical literature. Often when some one would tell of some piece of work he would cite something similar done twenty, thirty, fifty years before. The Society for Experimental Biology and Medicine was at first called the "Meltzer Verein." Dr. Meltzer's original idea was that it should be a society of workers, and that those who were not contributors should be dropped from membership, but owing to the exigencies of friendship this was not carried out. He suggested that the number of papers presented by one man should be limited and that it be made obligatory for every man to present a paper. As he advanced in years it was suggested that he might lighten his work. He said there were only two things that would stop him from working: if some one said, "Meltzer, your work is no longer good," or, "You can no longer understand younger men," then he would stop work. When they met to talk of establishing the Harvey Society he opposed the idea, saying New York was not a scientific center; there would be no audiences. A few days later he called Dr. Lusk up on the telephone and said he had changed his mind and had overcome all the objections which a few days before he had considered insuperable. A few years ago New York as a scientific center was a pretty bleak place. After a time, however, a few scientists met together and came to know each other socially, and the biologists and chemists after a while merged together as the Society of Experimental Biology and Medicine. After one of these early meetings Dr.

Meltzer had driven the speaker home and told him that he was going to the new Rockefeller Institute for Medical Research. He said his main desire was for experimental work. While in assuming the work there he fulfilled the desire of his life; at the same time he renounced the treasures of this world. Dr. Lusk said he mentioned this to him and Dr. Meltzer regarded him with disapproval. Few men at the age of fifty-five would have done likewise. He had met Dr. Meltzer in 1916, when he was greatly cast down by the war. He tried to prepare the way for peace, and the method he chose was based on the assumption that the medical profession, like the Red Cross, served friend and foe alike. Dr. Meltzer believed in the younger men of this generation. He was particularly interested in the American Association for Clinical Research, a society so revolutionary that it had been called the "Young Turk." He continually reminded us that we had not reached the level of accomplishment. Honest words of strong condemnation and criticism from Dr. Meltzer meant much to those who knew the texture of the mind behind them. He said last summer, when his health had failed, "My good friends insist that I leave my laboratory. Let me work in your laboratory." In the face of pain and suffering, the indomitable spirit of his mind could not be overcome. In closing, Dr. Lusk said he was grateful to have known Dr. Meltzer, who had added so much to New York as a center of medical science. His life was of value to us all. He had said "I am from the race from which came Jesus Christ." He was one of the few men of our time who possessed all the Christian virtues.

Dr. WILLIAM H. WELCH said it seemed as if every side of Dr. Meltzer's life had been touched upon and there was very little he could add. At the same time, he would have regretted not having come here and paid his tribute to one with whom he had been pleasantly associated since his arrival in New York in 1883. Both Dr. Meltzer and he had been pupils of Kronecker at Leipsic. There Dr. Meltzer had come under the influence and enjoyed the friendship of Kronecker which had continued until his death. Kronecker always took an interest in his pupils, and he loved Dr. Meltzer. Before Dr. Meltzer came to this country Kronecker had written to him (the speaker), telling him that Dr. Meltzer was arriving, and inquiring if it would be possible for him to get an academic position. It was scarcely correct to say, as Dr. Levene had said, that Dr. Meltzer did not desire such a position. At the time of Dr. Meltzer's arrival in this country the status of scientific medicine was such that he was soon disillusioned of these expectations. Dr. Welch related that during the past year he had had a letter from Dr. Meltzer, which was of a very intimate nature, telling of his birth in a small Russian city, and describing his family circle, and the circumstances which led him to leave Russia and go to Berlin and enter into another life, another spirit, and another world of thought. In 1883 he came to this country with his admirable ideas of medicine, but with his attention centered on the problems of physiology. He came with a letter from Kronecker to Dr. Welch's little laboratory, which for four or five years was one room in the old Bellevue Hospital. He was unable to give Dr. Meltzer a separate room, but gave him a corner in this room. Here he was faithful in his attendance, and together they did a little piece of work which, Dr. Welch said, was in reality Meltzer's separate work. This work was published, but he had never quite followed Meltzer in his broader views and elaborations based on that work, in which he insisted upon the importance of vibratory movements to living matter. His broader views on this subject were somewhat philosophical, due no doubt to his earlier philosophical bent. Dr. Meltzer left him to go to Dr. Prudden's laboratory, which had been started at about the same time that he had started his laboratory, and these were at that time the only laboratories where anyone desiring to do any kind of laboratory work could be accommodated. As Dr. Levene had said, these were the lowlands of medicine as compared with the heights of to-day, and in reaching these heights no small influence was that of Dr. Meltzer. In the laboratory of the College of Physicians and Surgeons, and in his own home at night, most of his laboratory work was done. He presented a marvelous

and almost unique combination, namely, that in the cultivation of experimental activities he was genuinely interested in the practice of clinical medicine. He had been a clinician more especially in the earlier and leaner years of his life, but at the same time he had done excellent work in the laboratory. As years went on he gave more and more time to experimental work. His life combined in a most wonderful manner the life of the real experimental physiologist, and at the same time that of the practitioner of medicine, and that without neglecting either. This was a very remarkable phenomenon. Dr. Meltzer must have exercised no little self-restraint not to have turned from the laboratory, and there were years not so prolific in experimental work, those in which he was establishing himself in a comfortable practice, but he never allowed himself to be drawn from his scientific ideals. Dr. Meltzer was one of the few earlier practitioners in this country whose practice was based upon physiological training, aptitude, and interest. Dr. Weir Mitchell was another, and, as Dr. Lusk had mentioned, the latter's father was a man whose work in obstetrics and gynecology was founded on physiological studies, and he made an excellent practitioner. In the early days when Dr. Meltzer came to New York the leading physicians were Abraham Jacobi, Alonzo Clark, Austin Flint, the elder Janeway, all interested in purely clinical studies from the anatomical side. And while the last to object to pathological anatomical studies, it was the functional and physiological side that they were coming to recognize as important. Dr. Meltzer typified this idea more than anyone else in the country. He lived during a time when there were great advances in medicine in this country, and especially was there a great improvement in medical education and in laboratories. It was also the period that witnessed the formation of various specialties; physiology was developed. Dr. Howell had told of the work of the Physiological Society. Not only was Dr. Meltzer interested in the work of the society, but in the establishment of a special journal devoted to the publication of technical research. This served not only to provide needed reading, but positively stimulated productive work. Then the *Journal of Experimental Medicine* followed, and then other publications of this nature. On the development of these publications Meltzer played an important part. His influence on the clinical side was not measured by his contributions to clinical medicine, but by the way he impressed one with the fact that clinical research was just as important and just as capable of scientific advancement as physiology. That was the great impression he brought into the science of the profession. Dr. Meltzer was one of those who realized that the younger generation was worth working with and trying to impress. The speaker was delighted to see so many of the younger men at this meeting because of the thought that they were drawn here by affection for a man who must have impressed his ideas upon them, not by precept alone but by example. He questioned whether it would be possible for a man devoted to laboratory work alone to have done this. Dr. Meltzer's great opportunity came when he was chosen chief of the Division of Physiology and Pharmacology of the Rockefeller Institute for Medical Research in its early days when it was important that the particular problems investigated should fall within a well-defined group of subjects. Here was a genuine physiologist with a wide reputation who was interested in those problems with relation to the practice of medicine, though he was the last man to advocate that practical utility should be the guiding principle in research. He was manifestly the expression of the combination that was ideal for the position. There he followed the great opportunities opened to him and did splendid work. Dr. Welch said he felt sure he spoke for all the scientific workers in the institute when he expressed their great appreciation of and debt to the work of Dr. Meltzer. He was glad to have had the opportunity to say a few words in memory of one with whom he had had a long continued friendship, and whose character he admired very much. It was well to come and pay our tribute to his memory and to call to mind his wonderful qualities of heart and mind and character, but it was better, and he would have so wished, to go away actuated by his desire to advance medical science and serve our fellowmen.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

MEDICAL COUNCIL OF CANADA.

Toronto, Winnipeg, and Vancouver, June, 1920.

(Continued from page 378.)

OBSTETRICS AND GYNECOLOGY.

1. Eclamptic toxemia: (a) Describe in detail the prodromal symptoms and signs; (b) indicate the appropriate treatment at this stage.
2. Occiput posterior: (a) Make the diagnosis; (b) give concisely the management.
3. Induction of labor: (a) What are the indications? (b) describe in detail any one method of induction.
4. Cesarean section: (a) Indications therefor; (b) the important points in the technique of the operation.
5. Prolapsus uteri: (a) State the anatomical lesions which may be present in prolapsus uteri; (b) what routine measures should be taken to prevent their occurrence?
6. Salpingitis: (a) What are the common causes? (b) indicate the course the disease may run; (c) describe the treatment in the acute stage, the chronic stage.

MEDICINE (INCLUDING THERAPEUTICS).

1. Enumerate the symptoms of the four most common complications which may occur in the course of typhoid fever. Give in detail treatment of two of these with prescriptions in full.
2. A note of impaired resonance is discovered in an area at the base of the right lung from the angle of the scapula downward. Give in detail the physical signs of four conditions which may produce such impairment.
3. Give etiology, symptoms, and prognosis in gastroptosis in a man forty-five years of age.
4. Discuss, briefly, the etiology, pathology, and therapy of chronic hypertension.
5. Enumerate the symptoms and signs which may be associated with (a) an acute lesion of the anterior horn cells; (b) a chronic progressive lesion involving the posterior columns of the cord.
6. State, briefly, your treatment of (a) Graves' disease; (b) impetigo contagiosa.

ANSWERS.

OBSTETRICS AND GYNECOLOGY.

1. ECLAMPTIC TOXEMIA—*Symptoms*: "Headache, nausea, and vomiting, epigastric pain, vertigo, ringing in the ears, flashes of light or darkness, double vision, blindness, deafness, mental disturbance, defective memory, somnolence; symptoms easily explained by the circulation of toxic blood through the nerve centers. These may be preceded by lassitude, and accompanied by constipation, or by diarrhea. Headache is perhaps the most significant and common warning symptom. In bad cases the urine is reduced in quantity (almost suppressed), very dark in color, its albumin greatly increased, so that it becomes solid on boiling. Next comes the final catastrophe of convulsions. The convulsive fit begins with twitching of the facial muscles, rolling and fixation of the eyeballs, puckering of the lips, fixation of the jaws, protrusion of the tongue, etc., soon followed by violent spasms of the muscles of the trunk and limbs, including those of respiration; hence lividity of the face and stertorous breathing, biting of the tongue, opisthotonus, etc. The fit lasts fifteen or twenty seconds, ending in partial or complete coma, possibly death; or consciousness may return, to be followed by other convulsions."—(King's *Manual of Obstetrics*.)

"The prophylactic treatment consists in frequent and regular examination of the urine. After the first appearance of albumin, daily quantitative examination of the urine should be made. The diet should be milk; the bowels should be kept freely open by means of calomel and salines; the skin should be kept active by hot baths, followed by vigorous rubbing. Diuretics, such as Basham's mixture, digitalis, and caffeine should be administered. During pregnancy, if the percentage of albumin increases in spite of the treatment, abortion or induction of labor is indicated."

2. OCCIPUT POSTERIOR.—*Diagnosis*: "Vaginal examination reveals the occiput and smaller fontanel posterior in the median line, while anteriorly the bregma is within easy reach. The sagittal suture corresponds to the conjugate diameter of the pelvis. If the complication be the result of an imperfect perineal floor, the head will be low down in the pelvic cavity, while if it occur from some insuperable obstacle to entrance into the superior strait, it will be found resting high up on the pelvic brim. Abdominal palpation will, in the latter class of cases, show an anterior median situation of the fetal extremities, with a transverse position of the shoulders; the head may be readily mapped out, while the fetal heart-sounds will be indistinct, and only heard far back in the flanks, or they may be altogether absent."—(Dorland.)

The normal course of delivery in occipito-posterior positions, is the same as in occipito-anterior positions except that the head must rotate to the front through three-eighths of a circle; of course this takes longer and is more tedious.

In abnormal cases, the management is as follows:

(a) *When diagnosed while the head is at the brim.*
(1) Leave it alone. The occiput will probably rotate to the front all right if it is given plenty of time. (2) If flexion appears to be deficient, try to increase it by pushing up the sinciput with the fingers in the vagina during a pain, at the same time pressing down upon the fundus with the other hand. (3) The head may be rotated by passing the hand into the vagina and grasping it between the fingers and thumb. At the same time the shoulders must be rotated by abdominal palpation, or else the head will at once go back to its original position. This maneuver generally requires an anesthetic.

(b) *When diagnosed after the head has entered the pelvis.* (1) Leave it alone. After exercising the patience of all concerned, it will probably rotate spontaneously. Only about one case out of twenty fails to do so. (2) An attempt may be made to increase flexion as before. (3) Manual rotation may be attempted as before, but the head must first be flexed and gently pushed back out of the pelvis. (4) If the pains are weak, forceps should be applied well back on the head, so that when traction is applied, flexion will be promoted. The head should then be pulled well down on to the pelvic floor. If it begins to rotate, take off the forceps and leave the rotation to nature, merely keeping the head on the pelvic floor by pressure on the fundus. After rotation the forceps may, if necessary, be reapplied and delivery completed.

(c) When the occiput has definitely rotated into the hollow of the sacrum and the case has become a persistent occipitoposterior, forceps should be applied and the head delivered with the occiput posterior. The perineum should be guarded as much as possible, and any tears stitched up at once. In extreme cases craniotomy and pubiotomy may require to be considered."—(Johnstone's *Textbook of Midwifery*.)

3. Conditions that justify the induction of premature labor: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of a fetus toward the end of pregnancy; (6) hydatiform mole; (7) habitually large fetal head.

Method of inducing premature labor: "Catheterization of the uterus: The first step consists in separation of the membranes from the lower uterine segment by means of a uterine sound or with the finger. The operation must be aseptic. Detachment of the membranes with the sound may be done with the woman in either the left lateral or dorsal recumbent position. For the use of the hand the dorsal position is best. The second step consists in the insertion of one or more No. 12 English bougies, or a sterile rectal tube, between the membranes and the uterus. No anesthetic is required. Usually the bougie or rectal tube is most readily passed with the aid of the Sims position, the Sims speculum exposing the cervix, which is drawn forward and held with a volsella. The bougie is sterilized by boiling or steaming, the proximal end is cut off, and a stylet inserted. To facilitate introduction the bougie is bent to nearly a right angle at about three inches from the distal end, giving it a large curve. Great care must be used to avoid rupturing the membranes. The in-

strument is then pushed up gently and in the direction in which it passes most easily. After it has entered between the membranes and the uterine wall, the stylet is drawn down about one inch. The flexible tip of the bougie finds its way readily with little risk of perforating the membranes. The bougie fully in place, the stylet is withdrawn. A second bougie may be inserted if it can be pushed into place without too much difficulty. Bleeding is probable evidence that the instrument has passed behind the placenta. The hemorrhage may occasionally be excessive. It is then best to withdraw the instrument and pass it in another direction. A light tampon of gauze may be packed in the vagina, but it is not required to support the bougie. The instrument is left to be expelled with the child. Labor usually is established within twenty-four hours. This method is not suited to cases in which immediate delivery is called for."—(Polak's *Obstetrics*.)

4. *Cesarean section*.—"Indications: The cases in which it is performed are: (1) Extreme deformity of the pelvis, in which delivery by forceps and version is excluded, and in which craniotomy is either impossible or would be more dangerous to the mother than cutting into the abdomen and uterus; and in which there is not room for a successful symphyseotomy. Such cases present the 'positive' indication for cesarean section; there is nothing else to be done. Flat pelvis having a conjugata vera of $2\frac{1}{4}$ inches or less, and justo-minor pelvis with a conjugata vera of $2\frac{1}{2}$ inches or less, present this positive indication; (2) cases of more moderate pelvic contraction in which craniotomy is possible, but cesarean section is agreed upon to save the life of the child; (3) mechanical obstruction in the pelvis from fibroid, cancerous, bony, or other tumors which cannot be pushed up out of the way or be safely removed; (4) irreducible impaction of a living child in transverse presentations; (5) in women dying near the end of pregnancy the child, if alive, is rapidly delivered by post-mortem cesarean section; (6) various other obstructions from inflammatory adhesions, atresia, constrictions, etc., of the vagina, and uterine displacements, may rarely require the operation; (7) recently the operation has been done in eclampsia cases, where more conservative methods of rapid delivery were impracticable; and (8) in placenta prævia, chiefly with a view to lessen the infant mortality attending the usual treatment of this complication."—(King's *Obstetrics*.)

Cesarean section.—"Fluidextract of ergot, mxxx, is injected into the thigh muscles just as the anesthesia is begun. The operator assures himself that there is no loop of intestine between the uterus and abdominal wall, beneath the field of incision. Should a coil of intestine be found there, it is pushed above the fundus. An assistant holds the uterus in central position. The skin incision extends one-third above and two-thirds below the level of the umbilicus. It is best made through the right rectus muscle. The external layer of the rectus sheath is divided, the muscular bundles separated with handle of scalpel and the fingers, and the deep layer of the sheath and the peritoneum divided after lifting them with tissue forceps. Bleeding vessels are controlled by gauze sponge pressure or held by catch-forceps before opening the peritoneum. A short longitudinal median incision is made in the uterine wall beginning at the fundus, avoiding the membranes if still unbroken. This is extended downward with fingers, scissors, or scalpel to a total length of about six inches. The hand is thrust through the membranes and the child is extracted by the head or the feet, whichever is most accessible. In case of anterior implantation of the placenta, usually the hand may best be passed directly through it. The cord is clamped at two points with catch-forceps, cut between them, and the child is passed to an assistant. The uterus slips out of the abdomen as the child is extracted, and the intestines are kept back with hot sterilized towels placed over the upper part of the incision. The coverings help also to protect the peritoneum from soiling. The uterus is wrapped in hot moist cloths. As a rule, it is better not to wholly evert the uterus. The placenta, if not spontaneously separated, may be peeled off by grasping it with one hand like a sponge. If the cervix is not sufficiently open for drainage, a large rubber tube or gauze strip is passed down through it and withdrawn from below. Irrigating or mopping the uterine cavity is unnecessary.

Asepsis is promoted by leaving it as nearly as possible untouched. The peritoneum is sponged dry with the least possible friction or handling. The uterine wound is closed with deep No. 2 chromated catgut sutures at intervals of about $\frac{1}{2}$ inch. They are given a wide sweep laterally through the muscular wall, falling short of the decidua. The peritoneal coat of the uterus is closed with a No. 1 continuous plain catgut suture, forming a welt over the deep suture line. The hemorrhage is inconsiderable and usually ceases with the introduction of the first sutures—a hypodermic of ergotole should be given before beginning the operation, and one of ergotole and pituitrin on the delivery of the child. Retraction of the uterus is ensured by manipulating it, if necessary, through a hot towel, or by faradism. When there has been much blood lost, a quart or two of warm sterilized 0.9 per cent. salt solution may be left in the peritoneum. The parietal peritoneum is closed with a plain running No. 0 catgut suture. Interrupted silkworm-gut sutures are then passed at intervals of about $\frac{1}{4}$ inches through all but the peritoneum, from within outward. The fascia is brought together with interrupted No. 2 plain catgut sutures, or with a continuous suture. The silkworm-gut sutures are now tied. The abdomen is cleansed, and the wound covered with a dressing of several thicknesses of dry sterile cheese-cloth; over this is placed a thick compress of sterile absorbent cotton. The dressings are secured with strips of zinc oxide adhesive plaster, and held in place by a Scultetus binder.—(Polak's *Obstetrics*).

5. *The anatomic lesions which may be present in prolapsus uteri*, are:—Lacerated perineum, relaxation and elongation of the ligaments of the uterus, subinvolution, cystocele and rectocele, and laceration of parts of the triangular ligament and various layers of the pelvic fascia.

The perineum should be protected during labor, examined after labor, and if lacerated it should be repaired; subinvolution should be guarded against.

6. **SALPINGITIS.** *Common causes:* Gonorrhea, septic infection, subinvolution, and certain diseases such as syphilis or tuberculosis. *Symptoms:* Pain or discomfort, made worse by pressure, examination, defecation, or colicky pains over the tube; dysmenorrhea; increased menstrual flow; tubes are found to be dilated and swollen. *Varieties:* Hematosalpinx, when tubes are distended with blood; Pyosalpinx, when they contain pus; Hydrosalpinx, when they contain serous fluid or exudate. The patient complains of a dragging sensation in the neighborhood of the affected tube; colicky pain, which is increased on exertion or even on standing; abdominal tenderness; menstrual disorders, as amenorrhea, metrorrhagia, dysmenorrhea, menorrhagia; dyspareunia; there may be septic symptoms and peritonitis; sterility generally ensues. On examination there will be found a fullness in Douglas' pouch and one or both lateral fornices; in these latter will be felt either the tubes, distorted and possibly adherent, or a sausage-shaped tumor, which is very painful; the uterus is retroverted or retroflexed, and may be bound down by adhesion; there may be an intermittent expulsion of pus accompanied and preceded by a burning pelvic pain. *Treatment of acute Salpingitis:* Rest in bed, hot vaginal douches, saline purgatives, liquid diet, morphine (if necessary) for pain, removal of pathological conditions and complications; radical operation (salpingectomy, or salpingo-oophorectomy) may be necessary. The chronic form requires removal of the tubes.

MEDICINE (INCLUDING THERAPEUTICS).

1. **COMMON COMPLICATIONS IN TYPHOID FEVER.** (1) *Intestinal Hemorrhage:* *Symptoms:* A sudden fall of temperature, followed by blood in the stools; there may be collapse. *Treatment:* Ice-bag over the cecum, hypodermic injection of morphine sulphate, gr. $\frac{1}{4}$. (2) *Perforation of the intestine:* *Symptoms:* Sometimes there is severe, sudden pain localized in the abdomen, and sometimes there is little or no pain. Marked tympanites, great weakness, collapse, anxious look, small, rapid pulse, and difficult breathing are present. The legs are apt to be drawn up, and nausea and vomiting may ensue. Hepatic and splenic dulness disappear, and leucocytosis may be present. *The treatment is surgical;* laparotomy, with suture of the intestine, should be done as soon as possible. In the meantime opium

(or preferably morphine) should be administered. (Morphine sulphate, gr. $\frac{1}{4}$). (3) *Bedsore.* And (4) *Pneumonia:* *Symptoms:* "The first stage is characterized by sudden onset with chill, a sharp pain in the side, rise of temperature, a short and sharp cough, rusty-colored, viscid sputum, and dyspnea. There may be headache, insomnia, scanty urine with diminution of urea, chlorides, phosphates, and sulphates, insomnia, and herpetic vesicles on the face, and there is always an increase in the number of leucocytes in the blood. Physical examination will reveal diminished expansion, impairment of the normal percussion note, feeble or suppressed respiratory murmur, moist or dry râles, crepitation, and sometimes a pleural friction sound. In the second stage the dyspnea is more marked; the face is more or less livid in color; the temperature is high (104° - 105° F.); and the pulse increases in rate (110-120), its tension and fullness lessening with the progress of the disease, and growing feeble and intermittent. Headache, delirium, and various other nervous symptoms may be present. Expansion is diminished and vocal fremitus is exaggerated upon the affected side. There is dullness with increased resistance over the consolidated lung, and auscultation detects bronchophony or bronchial breathing over this same area. The third stage is ushered in by a sudden drop of temperature on or about the fifth or ninth day, followed by a natural sleep, free sweating, and relief from suffering. In this stage the subcrepitant râle (râle redux) is heard in the midst of the bronchial breathing, together with numerous moist râles. Dullness may persist for some time, but usually by the twelfth or fourteenth day the lung has returned to its normal state."

2. **PHYSICAL SIGNS OF PLEURITIC EFFUSION.** *Inspection* shows immobility of the chest walls, with some enlargement on the affected side; the intercostal spaces may bulge, and there is displacement of the heart beat. *Palpation* shows the vocal fremitus to be absent. *Percussion* shows flatness or dullness, with increased resistance to the pleximeter finger. *Auscultation* shows absence of respiratory sounds except at the upper part of the compressed lung, where bronchial respiration and bronchophony or egophony are heard. Over the healthy lung the respiratory sounds are exaggerated.

The physical signs of empyema are those of fluid in the pleural cavity; that side does not move well, the percussion note is dull, there is absence of breath sounds, vocal fremitus and resonance are diminished.

Physical signs of pneumothorax: *Inspection:* "Bulging may be local or general on the affected side. *Percussion* usually yields a hyper-resonant or tympanitic note. If the valve-like opening be patent, a typical cracked-pot sound can be elicited. *Palpation:*—Absence of vocal fremitus. *Auscultation:*—Absence of breath-sounds. On coughing, the sounds produced are peculiarly amphoric and have a metallic ring. If the chest be struck with two coins whilst listening with the stethoscope, the characteristic bell or anvil sound is heard."—(Wheeler and Jack's *Handbook of Medicine*).

Impaired resonance is also found in the second stage of lobar pneumonia. See *Answer to Question 1*.

3. **GASTROPTOSIS IN A MAN OF 45 YEARS OF AGE.** *Etiology:* "The condition is predisposed to by imperfect development of the abdominal and other muscles and by their early loss of tension with wasting. Occupations which favor stooping postures, such as sewing, tailoring, shoemaking, etc., are important factors in its production. Relaxation of the abdominal walls, loss of abdominal fat, and abnormal descent of the diaphragm may cause displacement of the stomach.

Symptoms: "The patient complains of dyspepsia, abdominal distress and pain after eating, eructations of gases, anorexia, various nervous symptoms, weakness, and constipation. *Physical phenomena:*—In the standing position the lower part of the abdomen projects and the upper part sinks in. In the recumbent position the abdomen shows a lateral extension. Aortic pulsation is frequent. There is often a ridge lying across the abdomen to be determined by palpation. Inflation of the stomach often detects its prolapsed position with a lowered gastric splashing. The x-ray, with the aid of a bismuth subnitrate solution, will determine the location of the organ."—(From Hughes' *Practice of Medicine*).

Prognosis: This is good in mild cases; severe cases require operation, which may help.

4. *Chronic Hypertension.* "The pathogenesis is still obscure, as is also its precise relation to the associated renal and arterial diseases. . . . Whatever may prove to be the ultimate cause, its immediate cause must be either an increased output from the heart or an increased resistance to the escape of blood from the larger arteries." But there is no proof of an increase in the flow of blood, and the left ventricle is known to be hypertrophied; hence the immediate cause of hypertension is an increased resistance to the escape of blood from the arterial tree of the systemic circuit. Sclerosis of the larger arteries is not necessarily associated with an increased arterial pressure; the main resistance to the onward flow of the blood is not encountered in the larger arteries, but in the terminal arterioles and capillaries. There is frequently a sclerosis of the smaller arterioles; but the hypertension is not due to an anatomical narrowing alone, but to a narrowing that is in part caused by an increased tone of the muscle fibers surrounding the arterioles. (*Monographic Medicine.*)

Treatment. Prevention consists in the avoidance of severe exercise and excessive use of alcohol, tobacco, and of overeating. The patient should have his gastrointestinal tract purged; his diet and habits must be regulated; he should rest regularly, sleep well, and (if his blood pressure continues to rise) submit to venesection. Sodium nitrite in one half to one grain doses, or nitroglycerin (1/250 of a grain) may be given.

5. "*Lesions of the anterior horns* produce motor paralysis, but of the lower motor neuron type, of the spinomuscular type. This paralysis is restricted entirely to the particular group of muscles whose cells of supply in the anterior horn are affected, and usually in lesions of the anterior horns, instead of there being a complete extremity involved, or one isolated muscle, there will be a group of muscles. The clinical signs are (1) Atrophy, (2) loss of reflexes, (3) vasomotor paralysis, (4) fibrillary twitchings, (5) reaction or degeneration following electrical examinations.

"*Lesions of the posterior columns* produce sensory disturbances, especially as to pressure and muscle joint sense. All types of cutaneous impressions are delayed and there is a diminution of the sense of temperature and of pain. The clinical signs are ataxia, loss of deep reflexes, and paresthesia. These posterior columns degenerate upward and, therefore, the signs occur above the level of the lesion." (*Hunt's Diagnostic Symptoms in Nervous Diseases.*)

6. *Treatment of Graves's disease:* "Physical and mental rest, in severe cases rest in bed, fresh air, light, nutritious diet, and avoidance of stimulants are the general measures. Belladonna and bromides are useful sedatives, and the continuous application of an ice-bag may reduce the cardiac frequency. Sodium phosphate gr. xv to xxx thrice daily, sodium iodide, and arsenic have at all times been beneficial, and electricity to the thyroid is often useful. Application of x-rays to the gland has of late given good results, and is the most hopeful method of treatment, though there is some risk of subsequent thyroid insufficiency. Adrenalin and pituitrin have also been employed. In severe cases which are rapidly advancing, operation may be performed. Ligation of the thyroid arteries, and partial thyroidectomy are the favorite measures." (*From Wheeler and Jack's Handbook of Medicine.*)

Treatment of Impetigo contagiosa: The crusts should be removed, and an ointment of ammoniated mercury applied, care being taken that the ointment is not too strong; mild antiseptics may be applied to the surrounding areas. In children, means must be taken to prevent scratching the lesions.

(To be concluded.)

Persistent Virulence of the Nervous Centers in Encephalitis.—Harvier and Levaditi mention the case of a man who contracted epidemic encephalitis in January, 1920. On the following June he succumbed to cachexia with pseudo-Parkinson syndrome. Autopsy revealed lesions characteristic of the disease in the peduncles and locus niger. The tissues were virulent to rabbits although the virus had become attenuated. The incubation period, which ordinarily is but 5 or 6 days, was in this case 3 weeks. Passage through other animals did not increase the virulence.—*Le Progrès Médical.*

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

A HANDBOOK OF MIDWIFERY. By COMYNS BERKELEY, M. D. 550 pages with 74 illustrations. Published by Paul B. Hoeber, New York.

PRÉCIS DE MICROBIOLOGIE CLINIQUE. Par FERNAND BEZANÇON. 894 pages with illustrations. Published by Masson et Cie, Paris.

A SYNOPSIS OF MEDICINE. By HENRY LETHEBY TIDY, M. D. 952 pages. Published by William Wood & Co., New York.

MEDICAL SERVICE IN MODERN WAR. By P. S. BOND and C. F. MARTIN. 76 pages. Published by George Banta Publishing Company, Menasha, Wis.

FRENCH-ENGLISH MEDICAL DICTIONARY. By ALFRED GORDON, M. D. 161 pages. Published by P. Blakiston's Son & Co., Philadelphia.

CORNELL UNIVERSITY MEDICAL BULLETIN. Volume X, No. 2, October, 1920. 487 pages with illustrations. Published by Cornell University, New York City.

SURGICAL THERAPEUTICS AND OPERATIVE TECHNIQUE. Volumes II and III. By E. DOYEN. 1,491 pages with illustrations. Published by William Wood & Co., New York.

DISEASES OF THE NOSE AND THROAT. By HERBERT TILLEY, M. D. 844 pages with illustrations. Published by Paul B. Hoeber, New York.

THE TRANSACTIONS OF THE EDINBURGH OBSTETRICAL SOCIETY, Volume XL. Session 1919-1920. 147 pages with illustrations. Published by Oliver & Boyd, Edinburgh.

ZUR KLINIK DER HOHEN ZANGENOPERATION. Von S. E. WICHMANN. 156 pages. Published by Nordiskt Mediciskt Arkiv, Stockholm.

DAS EPOPHORON. Von S. E. WICHMANN. 224 pages with illustrations. Published by Suomalainen Tiedekatemianni, Helsingfors.

EXPERIMENTAL-BAKTERIOLOGISCHE UNTERSUCHUNGEN AN DURCH KAISERSCHNITT ENTBUNDENEN UND ASEPTISCH GEFFELTEN NEUGEBORENE. Von S. E. WICHMANN. 139 pages. Published by Suomalainen Tiedekatemianni, Helsingfors.

DERMATOLOGY. By WALTER JAMES HIGHMAN, M. D. 482 pages with illustrations. Published by The Macmillan Company, New York.

TREATISE ON GENERAL AND INDUSTRIAL ORGANIC CHEMISTRY. By ETTORE MOLINARI, M. D. 454 pages with illustrations. Published by P. Blakiston's Son & Company, Philadelphia.

A COMPEND OF DISEASES OF THE SKIN. By JAY FRANK SCHAMBERG, M. D. 314 pages with illustrations. Published by P. Blakiston's Son & Co., Philadelphia.

A SYNOPSIS OF SURGERY. By ERNST W. HEY GROVES, M. D. 620 pages with illustrations. Published by William Wood & Company, New York.

MANIC-DEPRESSIVE INSANITY AND PARANOIA. By Prof. EMIL KRAEPELIN. 280 pages with illustrations. Published by E. & S. Livingstone, Edinburgh.

GONOCOCCAL INFECTION IN THE MALE. By NORMAN LUMB, M. D. 328 pages with illustrations. Published by William Wood & Company.

DISEASES OF THE EAR. By PHILIP D. KERRISON, M. D. 596 pages with 332 illustrations in text. Published by J. B. Lippincott Company, Philadelphia.

GENERAL PATHOLOGY. By Dr. ERNST ZIEGLER. 594 pages with illustrations. Published by William Wood & Company, New York.

17TH ANNUAL REPORT, BELLEVUE AND ALLIED HOSPITALS, CITY OF NEW YORK. January 1, 1918, to December 31, 1918. 102 pages.

SURGERY OF THE LUNG AND PLEURA. By H. MORRISTON DAVIES, M. D. 259 pages with illustrations. Published by Paul B. Hoeber, New York.

THE AMERICAN YEAR-BOOK OF ANESTHESIA AND ANALGESIA, 1917-1918. Edited by F. H. McMechan, M. D. 483 pages with illustrations. Published by the Surgery Publishing Company, New York.

Miscellany.

NEW BOOKS AND OLD.

By JOHN RUHRÄH, M.D.,
BALTIMORE, MD.

Foreword.—This is to be a column of comment on books chiefly medical, not book reviews, but an informal, first person chat about things that cross the library table on their way either to the shelves or to the waste paper basket. Books, articles in journals, and other subjects which may appeal to what is so frequently referred to as the "cultural in medicine," will come within the scope of these occasional papers. The Editor of the MEDICAL RECORD has kindly consented to print a series of these little library table talks, but the future of this venture will depend largely on whether it finds a sufficient number of responsive readers. It is not my intention to be definitely instructive, not to do my readers' reading for them, but to suggest things which have interested me and which I, in turn, believe will be worthy of the attention of those interested in medical libraries, history and biography. It may be that this column may be the means of leading some neophyte to wander in what good old Richard de Bury, the patron saint of librarians, called "these pleasant fields."

The study of medical history is slowly but surely coming into its own in this country. For a long while it was a field worked chiefly by the Germans and, to a less extent, by the French and Italians, but now in England and America there are signs of an awakening to its importance, a recognition by others than specialists or semi-specialists. In America, amongst those who have stimulated an interest in this direction, Osler will easily be given first place. He did more to arouse and sustain an interest, not only in his students but in those who came into occasional contact with him. He founded, in Baltimore, the Book and Journal Club and the Johns Hopkins Historical Club. His essays on historical and biographical subjects are full of charm, splendid examples of his delightful style. It was due to his genial influence that a great many of his students and friends undertook the preparation of articles dealing with medical biography and history and his influence lives on and will continue to live, let us hope, for many years into the future. His magnificent collection of books relating to the history of medicine and the history of science, which is now being catalogued in Oxford, will eventually find its final resting place in McGill University of Montreal, where it will be cared for by a board of curators, and some scholar, as yet to be selected, will preside over it and help all who come in search of knowledge.

In a somewhat different manner a second personality has imprinted itself on American medical letters. The man now most influential in this country in matters historical is Lt. Col. Fielding H. Garrison, of the Library of the Office of the Surgeon General at Washington. To the cognoscenti nothing further need be said, good wine needs no bush; but he has worked so quietly that

the force of his influence may be overlooked or even placed elsewhere by those out of the current of medical letters. There are few publications of any note dealing with his subjects, medical history and bibliography, that are not graced by an introduction, biographical sketch or explanatory notes by this writer, who has so effectively, yet so quietly and modestly, helped to forward the work of others. Witness the reprinting of Choulant's "History and Bibliography of Anatomic Illustration, Translated and Edited by Frank," and "The School of Salernum, the English Version by Sir John Harington," to mention two of the latest publications. Of both of these, more at another time.

What I started out to do was to call attention to "The History of Medicine," by Garrison, now preparing for its third edition. To those about to embark on a voyage of discovery in the realms of medical history there can be no better guide. Garrison has done for medicine what Baedeker did for Europe, and he has done it with infinite charm. There is no one volume in English, nay, nor in any other language, where there has been brought together such a mass of fact, of detailed information, on the subject in question and told in such a readable, interesting manner. In every way the foundation stone of any library of medical works.

If you are a busy doctor with a taste for good novels there are two of the past year that can be highly recommended for the bedside table. "Main Street," by Sinclair Lewis, is well worth reading. It is a little long but one forgives that, it has many chuckles in it and some laughs. It has a medical interest, the chief male character is a physician. Note that I do not say hero. It is a novel without a hero or heroine. The characters in the story are just real people. If it has not already been given you, buy it and spend a pleasant evening.

The second recommendation is much shorter, a splendid story by Zona Gale, called "Miss Lulu Bett." Sketched in lines, and none too many, it is like a remarkable fine etching by Goya. A sort of caricature, but amazingly well done. The career of the old maid, hopeless and much imposed upon, with her success as a husband catcher is one of the cleverest things that has come out of America for many a long day.

11 EAST CHASE STREET.

Old Physicians and Surgeons of Bordeaux.—Durodié, who is one of the most indefatigable of medical historians, has contributed a paper on this subject to the *Gazette hebdomadaire des sciences médicales* for November 14, 1920, xli, 46. He confines himself to the XV and XVI centuries. The first of whom there is a record was a German named Ram who had taken his degree at Montpellier and had settled in Bordeaux. He arrived with a warm letter of introduction from Professor Colne of the Montpellier faculty and was licensed by the local examining board in June 1414. He arrived in time to serve as City Physician, the previous incumbent, a Spaniard, having recently succumbed to some severe malady. He had to defend a thesis before the Board which comprised *ex officio* the mayor and

assistant mayor. He made a brilliant success and at once became eligible to the salary of city physician, which was 80 Bordeaux francs per annum, a Bordeaux franc being equal to nearly nine of the present French francs. He was obliged to take an oath of loyalty to the French king, being of foreign birth, and another to the city to serve it faithfully. It is not meant that Ram was the first practitioner of Bordeaux, for there is evidence of others. Thus when Jean de la Poyada followed Ram in passing his examinations, it is recorded that his preceptor was one Pey Arben, a native practitioner of Bordeaux of whom nothing further is known. De la Poyada was licensed only a few weeks after Ram. We know nothing of his antecedents.

The regulations of the practice of medicine apparently did not begin until 1411, which accounts for the inception of our information at that period. A drastic regulation of November, 1414, made it necessary that every surgeon to be licensed must be the son or direct heir of a surgeon. If a foreigner, he had also to pass a rigid test and was subject to certain contingent penalties. Nevertheless there were numerous master surgeons and barber surgeons in Bordeaux in the XVI century. In 1508 the court physician was a naturalized Spaniard, one de Granolax who was succeeded by his nephew Lopez in 1551. In 1541 he had been able to buy a house, the property of a nobleman. In 1526 the pay of the city physician was increased to 200 Bordeaux francs, de Podio being the incumbent at the time.

In 1532 one Allepin, a stranger in Bordeaux, came to town to practise medicine and went before a Medical Board comprising de Granolax, de Podio, and two others. He failed and appealed to the jurats who ordered that he be given a new examination. This like all examinations was held in a certain convent. The author omits to state the outcome, but the question came up in 1556, in which the Board and jurats again clashed. The outcome was a letting down of the bars toward outsiders who wished to settle in Bordeaux. The friction, however, was by no means ended. We learn that there was a function, the "sermon of the master surgeon," a sort of oration delivered annually. Nothing further is known of it. In 1534 a druggist was charged with selling a drug which was accused of killing several people. Our old friends de Granolax and de Podio were two of three complainants. The druggist Laverigne was heavily penalized and ordinances were enacted to safeguard the public from the apothecary. The master surgeons occasionally got after the barber surgeons for breach of ethics. De Granolax, in addition to the post of Court Physician, also held the position of City Physician for years and his successor was voted for by the jurats who elected Pichot as having had more experience than a competitor Lataste. These extracts suffice to show that official and political medicine, despite the revolution of medical science, was not very different from that of the present day, 500 years later.

The Grassets, Father and Son, in Literature.—Voivener calls attention to the literary activities of Professor Grasset, the neurologist recently deceased, and his son Pierre, physician and novelist, in the Bulletin of *Progrès Médical* for November

27, 1920, xlviii, 48. The elder published nearly 500 articles during his lifetime and before his demise was at work on his "Dogme Transformiste," which has been edited by his son. It is a critique of the views of Darwin, Spencer, Haeckel, Le Dantec, and other biologists and of evolution and monism in general. The criticism is partly constructive, but Grasset belonged to that faction which does not believe in pushing evolution too far into human history.

The younger Grasset has published the following books: "Un Evadé de la médecine" (1906); "Le Journal de Pierre Daunis," a work of fiction (1908); "Un Conte Bleu," fiction (1910); the "Hymne à la Provence" to which Mistral wrote a preface (1912); and a three act play, "Jeannine." Since the war he has written "La Cœur et la Guerre" and "Aimer." The first-named consists of a series of three novels and the latter a romance of a biographical character. In all of these works the younger man had the advantage of his own medical training and of frequent conversations with his father on medicopsychological subjects. He was familiar with the writings of the Freudian school. In introducing psychology into fiction he has enrolled himself with the medical and neurological school of authors of imaginative works which includes Holmes, Mitchell, and other Americans.

Death of Professor Debove.—In the obituary of Dr. Debove in *La Presse Médicale* for November 17, 1920, xxviii, 86, his career is said to have been one of unusual brilliancy and his life unusually well filled. After graduation from a lyceum he began the study of medicine in 1869, and in 1873 his graduation thesis had for its subject buccal psoriasis. In 1877 he had become chief of clinic to the celebrated Germain Sée. He attached himself also to Ranvier, the histologist, and to Charcot. Among his histological researches he studied mycosis fungoides, cancerous lymphnodes, and myocardial sclerosis, while at the same period he published numerous papers on neurological subjects, including tremors, contractures, tabes, etc. Despite these early proclivities he became an internist like his master Sée, published studies on hepatic uremia, superalimentation, and tuberculosis, and was the first in France to take up examination of sputum in the diagnosis of the latter for Koch's bacillus.

Debove was also interested in the treatment of neuralgias by refrigeration, in a special technique for thoracentesis, in catheterization of the esophagus, in gastric lavage and feeding by the sound. It was inevitable that he should become one of the earliest gastroenterologists in France, and (with Rémond) he published a textbook on diseases of the stomach, along with monographs on gastric ulcer and lavage. He edited systems of manuals on medicine and diagnosis, clinical medicine, internal pathology, and therapeutics. He was a pioneer in social medicine with special reference to racial poisons—syphilis, tubercle and alcoholism. He became Faculty Professor in 1890 and in 1913 was made perpetual secretary to the Academy of Medicine. He succeeded Brouardel as Dean of the Faculty. He delivered the funeral orations of many distinguished colleagues and wrote well on episodes in medical history.

TEA INTOXICATION.

BY M. ALLEN STARR, M.D., LL.D., Sc.D.,

NEW YORK.

EMERITUS PROFESSOR OF NEUROLOGY, COLUMBIA UNIVERSITY.

THE custom of drinking tea is so universal and its usual effects, are so insignificant that it may not seem worth while to call attention to tea intoxication. Yet the subject is really of some importance, because of the increasing use of tea and because of the liability of physicians to overlook the fact that certain disagreeable symptoms may really be due to its abuse.

It may not be generally known that next to water tea is the beverage most widely used the world over. It was known in China as long ago as 2700 B.C., but was not brought into Europe till A.D. 1600. That it was quite a luxury at that time is shown by its price, for it sold in London in 1650 for £10 a pound. Pepys wrote in 1660: "I did send for a cup of tea, a China drink which I had never drunk before," a note which proves its rarity. But soon after this the East India Company began to import it freely and introduce its use in England and now statistics show that for every person in the British Empire six pounds of tea is required a year. In 1918 151 million pounds was imported into this country, making a pound and a half for every person, and as this is an increase of 40 per cent. over the importation of 1913 it is evident that the use of tea in the United States is increasing rapidly.

Acute cases of tea poisoning are extremely rare. Spillman (*Gaz. Hebdom. de Med.* 1901, Feb. 7), has put on record one interesting case.

A woman who, for some gastric disturbance had been advised to take a test meal of toast and tea, took by mistake 300 grams of tea in 300 grams of water. The active principle of tea being caffeine and the proportion of caffeine in tea leaves being 3 per cent. it was thought that she had taken about 9 grams of caffeine, or 135 grains. A fatal dose of caffeine for an animal is 1 grain to the pound. Within fifteen minutes the woman began to tremble violently, became very weak and fainted, had mild convulsive movements of the limbs and then vomited. The emesis continued for eight hours. She was pale and cold, had a rapid feeble pulse which after two hours became slow and remained at 40 for seven hours, gradually coming up to 80. Her respirations were shallow and rapid. Her temperature was subnormal, and her body was covered with a cold sweat. She was very restless, suffered from headache and mental excitement, but after eight hours became somnolent and by the end of twenty-four hours seemed to have recovered entirely.

This is the only case I can find in recent literature of acute poisoning. It is evident that the dangerous

effect was chiefly upon the circulatory and vasomotor systems, but that the motor system and cerebral activity were violently stimulated. It is interesting to note that in Sir James Mackenzie's book on the Study of the Pulse (p. 111) he states that he knew of a man who after an attack of influenza could not drink a cup of tea without his pulse intermitting every third or fourth beat for a short time and that this tendency persisted for several months. This effect upon the heart has been noticed by me in two cases.

H. C. Wood, in writing upon Caffeine, states that 12 grains is the largest amount that he had met with as having been taken by man. In that case in about two hours intense physical feebleness and a very uneasy condition of the mind were developed; very marked general muscular tremulousness soon followed, and the mental anxiety increased. After this passed off, there was obstinate sleeplessness, with active and persistent thinking and frequent urination. The brain power was stimulated very markedly. There was a diminution in the excretion of urea from 12 to 20 per cent., also in the elimination of nitrogenous matters.

While many chemists have stated that the active principle of tea, theine, is identical with caffeine, it seems from the very different physiological effects of tea and coffee that there must be some chemical differences in their active principles. This requires further investigation.

The following is an example of less acute poisoning:

Some time ago the captain of a college football team brought three members of the team to me in a state of great nervousness. These young men were well nourished—each weighed nearly 200 pounds—but were suffering from marked tremor of the hands, restlessness, insomnia, loss of appetite, indigestion in spite of the very careful and rigid diet of the training table, and nervous apprehension and depression of spirits. They had been treated for two weeks for indigestion by tonics containing strychnine, and the captain, having looked at the prescriptions, thought they were being poisoned by strychnine purposely given by the physician, who was an alumnus of a rival college, about to play the team. The nervous symptoms, the rather rapid pulse, the increased knee jerks, and excessive irritation of the nervous system in general made his theory of strychnine poisoning plausible. An inspection of the prescriptions of the tonics showed that the maximum dose of strychnine given was only 1/60th gr., quite inadequate to produce the symptoms, and the reputation of the physician in question made the theory absurd. On careful investigation I found that the athletic trainer had been giving the team large doses of tea. They were accustomed to drink it at breakfast and luncheon and before the practice hour two or three large glasses of fairly strong tea were given them. Thus each man drank at least two quarts of tea daily. The three men in question evidently had not been able to endure this amount as well as the others and were

suffering from tea poisoning. This supposition was confirmed by the result. For all the symptoms disappeared within a week when the tea was withdrawn.

I subsequently learned that it has been the custom of athletic trainers in many colleges to give strong tea before contests in tennis or ball or rowing.

It is well known that Swiss Alpine guides carry tea and urge its use in climbing mountains. When a night is spent in the mountain hut strong tea is given at the early rising meal, and tea is carried and given at intervals during any ascent.

In Russia, where tea is drunk more generally as a beverage than in any other country, those who are called upon to make muscular efforts are given tea in large quantity. During the war the English troops were freely supplied with tea and carried it instead of water in their canteens. The Americans preferred coffee, which they thought more palatable, and which contains the same or a similar principle. But aviators in both armies preferred to take tea before making hard flights.

Chronic tea poisoning is much more common than acute poisoning and may not always be detected. Sometimes, as in the following case, the discovery is accidental.

I was once consulted by an eminent colleague from Chicago regarding a nervous condition which had caused him much alarm. He had suffered from headache, and very persistent vertigo which caused a feeling of great uncertainty and swaying in walking. There was occasional tinnitus aurium. No affection of the ears could be determined and he naturally feared a beginning cerebellar tumor. This I could positively rule out, but was unable to ascertain the cause of his vertigo, and was not able to relieve the symptom by medicines. Some time afterward I received the following letter, which proved that the condition had really been due to tea:

"You may remember that last spring I consulted you relative to my own health—a certain confusion of the space sense with ringing in the ears and kindred symptoms. The trouble continued until last fall and although I have never been an excessive tea drinker (one or two cups a day) the entire difficulty disappeared upon giving up tea. I have resumed the tea repeatedly since, and the same symptoms have returned. Even a single cup of strong tea will produce them now. I am sure that the relation of cause and effect is clearly established and make this report under the impression that you will certainly be glad to know of my relief and possibly interested in its mode."

A patient was sent to me from Japan who was suffering from chronic tea poisoning. He had been for some years employed in the tea business as a tea taster. It was his habit to make an infusion of about a teaspoonful of each sample and take a tablespoonful in his mouth, taste it, and throw it out. In this way he often tested a hundred samples a day. He would chew a slice of apple between samples to eliminate the taste of the previous sample. He had gradually developed a condition of extreme nervousness, restlessness, mental depression, and insomnia with tremor of the hands, attacks of headache and vertigo. He had palpitation of the heart with a rapid irregular pulse. He had complained of loss of appetite, indigestion, and constipation for a long time before the nervous symptoms appeared. When he arrived in this country after the four weeks' trip from Japan all the symptoms mentioned were persistent and he was in a state of extreme neurasthenia. It was not until after three months of rest, care and hydrotherapeutic treatment that he finally recovered. The insomnia was the most distressing symptom of all and did not yield to ordinary hypnotics. As he had always been of a cheerful disposition his depression seemed also traceable to the tea.

That mental symptoms may possibly be caused by an abuse of tea has not been generally recog-

nized, but in the reports of asylums in Ireland I find that excessive tea drinking is mentioned as a cause of insanity. The Irish alienists state that the characteristic symptoms are insomnia, periods of despondency alternating with states of anxiety, and great restlessness. These cases may perhaps be ordinary cases of manic depressive psychosis in a tea-drinking people. Yet the influence of tea in their production has been affirmed by competent men.

These facts have convinced me that the influence of tea in causing certain nervous symptoms should not be disregarded. In the *MEDICAL RECORD* in 1912 James Wood of Brooklyn, published a study of the effects of tea among Irish servant girls in his dispensary practice and came to the conclusion that about 10 per cent of the cases of ordinary ill health among this class are traceable to tea. The symptoms manifested in the order of frequency were headache, vertigo, despondency, palpitation of the heart, indigestion, insomnia, restlessness, mental confusion, constipation, loss of appetite, and tremors. These girls were accustomed to drink tea more or less all day, often taking as many as 12 or 15 cups daily. Several women, who were keeping house, admitted to using a pound of tea daily—others had tea boiling on the range all the time, and took a cup at frequent intervals—all took more than 5 cups a day. In all the cases treated the symptoms subsided as the tea was abandoned. In many cases the diagnosis of the cause had been overlooked, and the treatment had been directed to the indigestion or to the headaches and general nervousness without result. Too often in our dispensaries such cases are dismissed with a mixture of rhubarb and soda and the true cause is not suspected. Even in private practice such cases may occur and the true cause may be overlooked.

Is there any reason for the general use of tea and what is the agreeable effect which has led to its use? Hoch and Kraepelin in 1895 made a careful study of the bodily and mental results of the use of substances containing the active principles of tea. They showed that during the first hour after an appreciable dose of strong tea there is a marked increase in muscular power and endurance. This began about twenty minutes after the tea was taken, reached its maximum in an hour, and lasted several hours. It is well known that the mental effects of tea can also be measured. There is a more rapid train of thought, an increased association of ideas, keener appreciation of things read or heard or seen—and a mental stimulus which they estimate as an increase of mental activity during the first hour of from 5 to 8 per cent. There is a sense of increased power which is attended by a pleasurable sensation, a feeling of brightness, cheerfulness, and mental activity—not perhaps as rapidly developed or as intense as that produced by alcohol, but quite comparable.

I hesitate to put this on record lest a wave of tea prohibition be started which may overwhelm the tea addicts. It is a result, however, which explains the growing and almost universal use of tea, especially in the late afternoon when the fatigue, both physical and mental, of the day seems to make one desirous of an artificial stimulant. It would be foolish to assert that this is in any way harmful

in moderation. But an occasional case of tea-intoxication may occur, and unless the physician is aware of its possibility it may be overlooked. On the other hand, general experience, clinical and laboratory, derived from the study of cases, and personal from the social use of tea leads us to the conclusion that much solace and satisfaction is to be obtained from "the cup which cheers but not inebriates."

5 WEST FIFTY-FOURTH STREET.

DIAGNOSTIC POINTS OF VALUE FOUND IN THE URINE.

By WILLIAM HENRY PORTER, M.D.,

NEW YORK.

PROFESSOR EMERITUS IN PATHOLOGY AND INTERNAL MEDICINE
AT THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL

To distinguish normal from abnormal functioning is exceedingly simple, so much so that even the fastest runner may differentiate them, if he will but keep his eyes open while he is running. That the distinction is not evident to every medical man, however, is only another proof of the superficiality of our knowledge of the vital principles of chemistry.

Man, as Crile well says, is merely an adaptive mechanism; he is, nevertheless, a mechanism run on immutable chemical formulæ, the operation of which formulæ is accurately registered in the urine. If the urine is free from indican we know that there is no putrefactive fermentation going on in the intestinal canal nor in any other part of the body. If there is no overproduction of uric acid, and if the ratio between uric acid and the urea elimination is normal, we know that the protein substances are being thoroughly oxidized. If there is no over-elimination of phosphates we know that the nervous mechanism is assimilating normally.

When the physiological economy is working perfectly the urine is free from indican. At the same time it must be remembered that the urine almost always contains a trace of etherial sulphates; so that if there is the slightest amount of putrefactive fermentation in the intestinal tract, a trace of indican will be found in the urine. Under these circumstances, in our reports of urinary findings, the term "trace of indican" should be used instead of "indican normal," so often seen. Beyond this point the record should read "a pronounced trace," or "abundant," or "very abundant," as the case may be. If so recorded an accurate knowledge is obtained as to the amount of the putrefaction taking place in the intestinal canal. The chief reason for being so exact in regard to the indican question is the fact that indican when correctly reported is a true guide to the proper functioning of the digestive and hepatic systems. Through the indican we can determine whether our patients are on the correct diet or not, and also when our therapeutic agents are producing the desired results.

By a similar token, any deviation in the uric acid balance, indicated by an over-production of uric acid, is also abnormal. This over-production of uric acid may not be of any immediate pathological significance. On the other hand, unless the cause which produced the over-production can be detected and corrected, the over-produced uric acid may be

indicative of the development of even grave structural changes in vital organs.

If there is an over-elimination of phosphates, either with or without oxalates, we know positively that there are mal-nutritive conditions affecting the nervous system, unless the patient happens to be taking an excessive amount of phosphates; as, for

TEST FOR INDICAN

Take 10 C.C. of urine, 10 C.C. hydrochloric acid and 5 drops of 1/2% solution potas. permangan. and shake. Then add 5 C.C. chloroform and shake. Purple coloration followed by deposit of blue pigment shows presence of indican.

FIG. 1

instance, when the phosphates are administered freely as medicine, or when the patient is on an unusually liberal diet of vegetables.

Principal Varieties of Indican.—When the indican test is applied to a sample of urine there are many gradations in the color reaction that may be obtained. Fig. 1. These are so classified that they will have a practical application to the clinical picture that the different colors represent. Every physician should be able to distinguish simple indicanuria, in which the test gives a clear indigo blue color, and which indicates that there is a simple putrefactive fermentation taking place in the intestinal canal, one in which there is very little toxic absorption from the lumen of the intestine into the blood stream. This process is expressed by the following equation:

Then we meet with an indican class in which the color is a decided purple. When this results, there is more or less toxic material produced in connection with the fermenting process, the system being poisoned by the absorption of the toxins. Now we have a true toxemia to deal with.

We meet with other cases in which the color obtained is a bluish black or almost black. The darker the color the greater the intensity of the toxemia.

Then we have the red indicanurias, expressed by the following equation:

The formula of indigo red is

In this particular type of indicanuria the indican is not precipitated, as is the case with the blue forms, but the result is a very pronounced reddish coloration of the urine in the test tube above the surface of the chloroform, while the chloroform itself remains colorless.

Quite frequently the application of the indican test results in a greenish coloration of the chloroform below the line of demarcation between it and the urine above. When this develops it indicates that the internal ends of some of the capillary bile ducts within the liver are occluded. Instead of the bile reaching the intestinal canal as it normally does, it works back into the lymphatic spaces surrounding the hepatic cells and ultimately reaches the blood stream by the thoracic duct. Its final elimination from the system is through the kidneys. It is quite possible that the biliverdin so excreted may in part account for the green coloration.

In case the patient is taking iodide of potassium and there is no indican present in the specimen under examination, the reaction to the ordinary indican test gives a clear cherry red color to the chloroform. On the other hand, if the specimen contains

plied, there is invariably a sharp line of demarcation between the chloroform and the superimposed layer of urine. On the other hand, if assimilation is impaired a more or less opaque disc forms at the junction of the two fluids—the urine and the chloroform. This disc will vary in thickness from an eighth of an inch to an inch. It may be situated largely in the urine above the line of junction, or the disc may be below the line of demarcation, lying wholly within the chloroform zone. Upon the character and situation of this disc, we can determine different grades of malassimilation.

The Porter Metabolism Test.—This test, when properly applied and interpreted, determines also the state of the metabolism, whether perfect or imperfect, and also indicates the degree of imperfection. This peculiar reaction giving rise to the disc formation, as already described, is noticed in connection with the ordinary indican test. It develops as a result of adding equal quantities of urine and chemically pure hydrochloric acid in an ordinary test tube, then adding 8 or 10 drops of one-half per cent. solution of permanganate of potassium, and then (depending upon the size of the test tube) from one-half to one dram of chloroform. The test requires from twenty-four to forty-eight hours for its full development, which emphasizes the inadequacy of this metabolism test when superficially and hastily made.

When dissolution is imminent a peculiar flocculent material develops in association with a fairly large amount of indican, or even in the absence of indican, shading in color from a light gray to almost black. This flocculent and oil-like matter is often observed in the absence of indican. Upon microscopic examination, it is found to be composed of two distinct types of material, one part consisting of fine granular matter, which when abundant, masses together and collects above the level of the chloroform. The other substance is composed of this same granular material in conjunction with numbers of large and small globules resembling fat globules under the microscope. When the latter predominates it collects as a white, snow-like mass, which seems to fall below the level of the junction of chloroform and urine. When the light gray, flocculent material forms above the junction of the chloroform and urine, numerous fat-like globules are present in some instances, in conjunction with or enmeshed in the simple granular matter.

When this flocculent matter is dark and solid it is usually composed entirely of this granular material, the fat-like globules being absent, thus explaining the various ranges of coloration observed in conjunction with the application of this test. When this matter is very dark and abundant, and forms rapidly it is seen above the level of the chloroform, it is of grave prognostic import; for death is sure to ensue within a very short time, unless this can be speedily overcome. My experience with this reaction, extending over a period of ten years, proves conclusively that this peculiar condition cannot be permanently eradicated. Hence we are in the habit of speaking of it as the "dead line" in the urine. On the other hand, when the flocculent ring is white and "snowy" and beneath the level of the chloroform, it indicates varying

FIG. 2.—Indicanuria test, showing variations in assimilation. 1, Normal; 2, slight malassimilation; 3, marked malassimilation; 4, beginning dissolution, or the "dead line"; a, line of demarcation; b, urine; c, chloroform.

indican, the color reaction will be modified, being reddish blue, reddish purple, or reddish blue-black, or even black.

Perfect and Imperfect Assimilation.—When the assimilation is perfect and the indican test is ap-

degrees of disturbed metabolism, depending upon the depth and density of the ring. And now the prognosis is always good.

During the past summer Professor John William Gies made an extensive study of these precipitates and his report is as follows:

During the course of this work, you called my attention to a peculiar precipitation you had frequently obtained in applications of the ordinary chloroform-acid test for indican. You observed, you said, that when such mixtures (that is, urine, hydrochloric acid, a weak solution of permanganate of potassium, and chloroform) were allowed to stand, a heavy, dark flocculent precipitate collected above the chloroform in the urine of patients suffering from nutritive disturbances who were approaching a fatal termination, but did not appear under similar conditions in the urine of normal people, or of patients whose diseases did not involve serious nutritive disorders. You also stated that a white oily precipitate frequently appears in such mixtures in the upper part of the chloroform but *within the range of the chloroform*, this precipitate showing special tendency to adhere to the side of the vessel in which it is separated.

At your request, I endeavored to determine the nature of the dark precipitate that forms, under those conditions stated, immediately above (and that rests upon) the chloroform. You sent me urine from several of your patients for this purpose. I found that this substance is a modified form of coagulable protein and that it consists of a mixture of modified albumins and globulins, presumably from the *blood* of the individual affected.

I have been unable to obtain enough precipitated material to determine satisfactorily the character of the white precipitate that frequently is produced in the upper part of the chloroform zone, under the conditions stated above.

For the full development of these peculiar reactions relating to assimilation, the specimen of urine under observation, when so tested, must be permitted to stand for from twenty-four to forty-eight hours for the full development of these reactions. Failure to follow this time procedure is, in my opinion, the reason why these important and valuable results have not been more generally observed. Unless the specimen is kept under observation for a sufficient length of time to permit the development of these reactions, these diagnostic and prognostic points will be lost.

Harmless Versus Toxic Uric Acid.—The imperfect reduction of the protein molecule is evidenced by an *over-production* of uric acid. This is accurately indicated by a test which it was my privilege to discover thirty years ago and which I have used almost daily since. When the protein molecule is perfectly oxidized in connection with the physiological working of the human economy, there is no over-production of uric acid. With imperfect oxidation, however, there is a varying degree of over-production, depending upon the amount of free uric acid excreted.

It is not generally known that there are two distinct types of over-produced uric acid. One form results from simple over-eating, or from a deficient supply of oxygen, but without a general toxic condition of the system. In this variety the uric acid is spontaneously deposited, simply on account of its high insolubility, shortly after the urine has been voided and allowed to cool.

The other type is associated with a decided toxic condition of the system. In this form the antecedent protein molecule from which the uric acid molecule is produced in the cells of the kidneys, is

a highly toxic one and gives rise to more or less profound clinical symptoms. (Fig. 3.)

This particular type of uric acid for some as yet unexplainable reason, is often held in solution in the urine for several days, even when it is present in considerable quantities. Its presence, so far as I know, can be readily shown to exist in the urine only by the application of my test for determining the presence of over-produced uric acid.

The Porter Test for Over-produced Uric Acid.—

Fig. 4. Schematic drawing showing single (a) uriferous tubule from Malpighian tuft to papilla or its outlet, (b) Malpighian tuft and blood vessels, (c) First convolution, (c) Descending arm of loop, (d) Henley's loop, (e) Ascending arm of loop, (f) Second convolution, (g) Straight or collecting tube. Uric acid is dropping into the tubule from the side, 2. Neutral phosphate of soda molecule as it unites with the uric acid to form 3. The acid phosphate of soda; and 4. The salts of soda formed by this chemical mutation. Cell I, the cell on the left side of the tubule, is the cell on the inside and the blood vessel on the opposite side, illustrating normal oxidation of protein molecule within the protoplasm of the cell. The protein and oxygen coming from the blood into the cell, where the oxidation is taking place, produces the uric acid dropping into the lumen of the tube, while the carbon dioxide flows back into the blood. All the other reduction products dropping into the tube as does the uric acid. The cell II, the cell on the right side of the tubule, is identified as cell II illustrating abnormal or suboxidation in the renal tubule. Urea diminished one half while the uric acid is overproduced fifty per cent. In both the normal and abnormal oxidation of sulphur is added in the urine as a sulphate. The sulphuric acid is produced from the reduction of hydrogen. Cell II, when it reaches the urine, is in the form of a sulphate, Na_2SO_4 or "Glauber's" salt. This salt being produced in connection with the oxidation reduction of the protein ele-
mentary sulphur, is added to the urine in the process of producing sulphuric and hydrochloric acid.*

For those who may not be familiar with this test it may be stated that it consists in boiling the super-strata of urine in the test tube, and then adding a very dilute acetic acid solution; so dilute that even in the presence of heat it will not decompose the normal urate of soda, or any other urate contained in the urine. A 4 per cent. solution is

*Porter, Wm. H., The Therapeutics of Decreasing Body Alkalinity, MEDICAL RECORD, September 18, 1920, p. 471.

recommended. Emphasis is placed upon a *weak solution* from the fact that ordinary hydrochloric acid or any other strong acid, will decompose the normal urates in the urine, with the formation of uric acid crystals.

After boiling the urine, adding the few drops of the dilute acetic acid solution, and re-boiling, the test tube and its contents must be allowed to stand in a cool place for from twenty-four to forty-eight hours. During this time, if there is an over-production of uric acid, the uric acid crystals will begin to form just underneath the free surface of the urine. The crystals appear to hang, as it were, from the surface of the urine. When formed rapidly and in large quantities they will in part drop to the bottom of the fluid.

By the amount of uric acid and crystals present we can estimate the relative percentage of uric acid contained in a given specimen. If one wishes to make this test quantitative, it is necessary to collect the crystals on a weighed filter, dry, and re-weigh. This is, in my opinion, the most simple and accurate of all the devised tests for both qualitative and quantitative estimation of over-produced uric acid. So far as I know, it is the only test

TEST FOR OVERPRODUCED URIC ACID

After boiling the upper strata of urine add a few drops of 4% acetic acid. Let it stand for 3 or 4 hours, after which the overproduced uric acid will crystallize out just beneath the surface of urine in test tube.

FIG. 4

that determines *only* the over-produced uric acid. It is unquestionably the best one for the general practitioner.

Urea Elimination.—The study of the over-produced uric acid is more valuable than estimating the total of urea eliminated. This is especially true if we wish to know whether the protein molecules are perfectly or imperfectly oxidized.

The determination of urea as it is ordinarily done, by simply estimating the percentage in a small quantity of urine, without any knowledge of the total quantity of urine passed during the twenty-four hours, is of no value whatever. Even if the total twenty-four hours amount of urine is known, estimation of the urea is of no practical value, unless the examiner knows also the total amount of nitrogen ingested and assimilated. Even with all this knowledge, when studying the urea output, the estimates must be made for several days in succession for anything like a practical working knowledge.

From such a study it is clear that if the patient is on a very low protein diet, the elimination of urea must be small; or else the fixed protein must be

breaking down with undue rapidity. The same is true, in many instances, when one is living exclusively on a vegetable diet.

In some cases of pregnancy, in which the intake of protein is low, and when a part of the protein that is ingested is constantly entering into the building-up of the fetus in utero, the urea output is also very low; a condition which on many occasions has unnecessarily alarmed the obstetrician, a subnormal physiological condition being mistaken for a truly pathological one. The use of a low protein diet, as advocated by some obstetricians, to keep the child small and make labor easier, is taking an undue advantage of the helpless fetus in utero.

More than forty years ago, at the time Weston made his famous six days walk in Madison Square Garden, the attempt was made to determine the nitrogen output for the week by estimating only the quantity of urea excreted every twenty-four hours. The statement was made at the time that as the result of this tremendous physical exertion there was less and less urea excreted. As it was then interpreted, it proved that over-exertion did not necessarily greatly augment protein destruction.

Two points in this connection should always be remembered; first, that over-exertion always increases the uric acid elimination and decreases the urea. Therefore, if we wish to determine the nitrogen output more accurately we must compute both urea and uric acid; and we must remember the fact also that each uric acid molecule carries twice as much nitrogen out of the system; so that augmentation of the elimination of uric acid takes considerable nitrogen with it. Second, that the output of nitrogen is more largely governed by the amount of protein contained in the foodstuffs than it is by the breaking down of the proteins within the body. In fact, however, over-physical exertion demands a larger supply of protein, and hence the system eliminates more nitrogen.

Phosphates: Over-Elimination and Significance.—To determine the over-elimination of phosphates, boil the super-strata of urine in the test tube. If there is an over-elimination, a white, cloudy opacity occurs, which at times has been mistaken for albumin. The addition of a few drops of a four per cent. solution of acetic acid, however, will differentiate between the two, for if this precipitate is due to an over-elimination of phosphates, it will rapidly vanish on addition of the acid; whereas if it is due to albumin the precipitate becomes more intense.

To detect the oxalates which are often present in connection with phosphaturia, the specimen must be examined microscopically, when, if oxalates are present, the oxalate of calcium crystals will be readily seen.

With a simple phosphaturic condition, it indicates a mal-nutritive condition of the nervous system, and is evidenced by general weakness and lack of nervous energy. When the overproduction of phosphates is associated with the oxalates, the symptoms are likely those of the so-called neurasthenic type.

Lethal and Harmless Varieties of Glucose.—It is interesting also to note that in glycosuria there are two types, distinctly differentiated by uranalysis. In one of these types the glucose as found in the urine is the result of extrinsic causes, such as eat-

ing too much, inability to oxidize, lack of out of door exercise, and so forth. In the other type of glycosuria there is some well defined intrinsic change, which always plays an important role in the production of the glucose and its presence in the urine.

I have gone into certain associated phases of this matter very extensively in my book "Eating to Live Long"*, and have considered very carefully the etiological relationship between glycosuria and the over-production of uric acid in these conditions.

While we use the same test (the Trimmer test) to determine the presence of glucose in the urine, there is a decided shade of difference in the reaction secured in the two varieties. In the extrinsic type the reduction of the copper is effected slowly; it at first assumes a dirty yellow aspect; and it often requires an hour or more before the well-known brick-dust colored deposit is evident. In the intrinsic variety, however, the brickdust reaction is almost instantaneous, and the deposit very rapidly produced. This difference in reaction is probably due to the fact that the $C_6H_{12}O_6$ molecule is known to exist in seven or more different isomeric forms: that in connection with these different results following the application of Trommer's test, we have, in one instance, one of these seven $C_6H_{12}O_6$ different isomeric forms of glucose-like molecules, and in the other a still different isomer.

It is a well established clinical fact also that the prognosis is good in the first type, whereas in the second form the condition is quite likely to prove fatal within a short period of time. This is especially true in young subjects.

Three Types of Albumin and Their Significance.—With albumin, as with indican and glucose, the urinary test discloses several types of protein reaction. The very translucent type of albumin indicates merely a slight disturbance in metabolism, but without retrograde changes in the kidney cells, either present or proximate.

A second type, which is decidedly opaque, is seen in varying amounts.

Then there is a third type in which the precipitate is in the form of a highly caseous, dense mass. This form usually indicates a pronounced parenchymatous metamorphosis taking place in the renal cells, and that the case is of a serious nature. It is usually most pronounced in syphilitic cases; less fatal, however, in this connection than in the absence of this infection.

Occasionally we meet this form of albumin in cases in which there is little or no degenerative change going on in the renal cells. When this is the case, there is no extensive degenerative change in the renal cells lining the uriniferous tubules, a sufficient number of cells, retaining their full physiological vigor, remaining attached to the basement substance.

Unless these different kinds of albumin are distinctly differentiated, and so stated in the report of the uranalysis, it is impossible to judge accurately just what the nature of the metabolic process is in the case under observation. To say simply, "albumin present," means almost nothing so far as giving a clear picture of the pathological processes is

concerned. Both the kind and relative amount found should be clearly stated.

Another pertinent fact in connection with this class of work is the necessity for analyzing a night and morning sample for at least three days in succession. In some instances it may be necessary to continue the twice daily observations for a week at a time, if the internist is to become fully conversant with every phase of these complex metabolic disturbances.

The reason for this is the fact that the abnormal changes fluctuate with extraordinary rapidity; so much so, that within a few hours the metabolic changes will be diametrically opposite, and the condition of the urine may be changed from one indicating a normal to one that is abnormal and vice versa. For example, a night specimen may indicate an abnormal condition, while a sample of the following morning may be nearly perfect. In adolescents, albumin may appear only at certain times of the day and be absent in the morning and at night. Knowing these facts, the only accurate method of arriving at an opinion of any true value is to insist upon examining a series of samples, or separately a sample from each urination during the day, and then striking an average.

It is only in conjunction with an intimate knowledge of all the clinical details and idiosyncrasies of the patient by the one who makes the urinary analysis, that these fine gradations and their full significance can be fully comprehended.

Microorganisms of Diagnostic Value.—There are but three microorganisms that are of real value as aids to diagnosis in connection with urinary analysis, namely: the colon-typhoid bacillus group, the gonococcus, and the tubercle bacillus. As regards the colon bacillus, little time need be spent in determining its presence in connection with pyelitis, since Lenhartz (Mikros. u. Chem., 9te Auf., Berlin, 1919, p. 384) has proved that more than 90 per cent. of such cases are due solely to this bacterium. Cases due to the presence of other microorganisms are rarely met with. Aside from the gonococcus and tubercle bacillus, determination of the species of cocci or bacilli present in voided urine is useless from a practical or therapeutic standpoint, and even of scientific value only in aseptically obtained urine; because there is no specific therapy based upon the species of infectious bacteria. Therefore, to ask the bacteriologist to search for other kinds of microorganisms is largely to waste his time and also to impose unnecessary expense upon the patient. In the case of gonococci and tubercle bacilli, however, determination is absolutely essential, both diagnostically and therapeutically.

In connection with all these facts, it may be said that to be an accomplished diagnostician and internist necessitates that, in addition to being thoroughly trained in urinary analysis, one must have intelligently performed a large number of necropsies. The number should run well into the hundreds; the number can never be too large. The more the examinations are made upon subjects who during life were directly under the care of one who makes the necropsy, the greater will be the knowledge thus obtained. At the same time that the case is under observation, the physician in attendance should personally conduct the analysis of the urine along the

*Porter, Wm. H.: "Eating to Live Long," 2 ed. Reilly & Lee Company, Chicago, 1920.

lines indicated in this paper. In no other manner can the physician learn how to interpret accurately the urinary findings which dovetail together with the symptoms with absolute precision. Evidence of what is transpiring within the system is usually recorded in the urine in advance of the objective symptoms, thus often forewarning the clinician of that which later will be observed at the bedside.

After the physician has become proficient in these three fields, he can easily learn how best to arrange the diet for his patient; for he knows full well how these morbid processes are brought about and what is necessary to combat and overcome them. In like manner, he knows how best to select his therapeutic remedies, and he then becomes a thorough expert and scientific and practical therapist. Empiricism in a complete measure disappears, the use of his remedial agents becomes more exact, and the results of his endeavors more certain and satisfactory to his patients.

ALVEOLECTOMY.

A SURGICAL PROCEDURE FOR THE TREATMENT OF TRIFACIAL NEURALGIAS OF LOCAL ORIGIN.

By S. SIDNEY GROSS, D.D.S.,

NEW YORK.

INSTRUCTOR IN THE DEPARTMENT OF ORAL SURGERY AND CONDUCTION ANESTHESIA, ADVANCED COURSES FOR PRACTITIONERS, COLUMBIA UNIVERSITY; ATTENDING ORAL SURGEON TO THE METROPOLITAN HOSPITAL.

ALVEOLECTOMY is the surgical removal of the diseased or the jagged buccal or lingual portions of the alveolar processes of either the upper or lower jaw. The proper application of this procedure in the treatment of trifacial neuralgias of local origin has proved to be of great value.

Neuritis of one or more branches of the trigeminal or 5th cranial nerve (trifacial neuralgia) is said to be the most painful of human maladies; the neuralgia is most excruciating, and the suffering most intense. Primarily it is not a disease, but the nerves express pathological disturbances general or local in some part of the anatomy of the head and neck.

Etiology.—The nerve trunks may undergo degeneration from long continued irritation, which when once fully established becomes an entity in itself. Most cases of trifacial neuralgia occur either during middle life or advanced age. They become active with the advent of fall and winter continuing until the weather settles, at which time the paroxysms become quiescent. Females are inclined to be more susceptible to the attacks of neuralgia than males, the condition prevailing more among inhabitants of crowded cities than of country districts.

Neuralgia is the sequel of either general or local disturbances. The general causes are the toxemias of infectious diseases. The local causes are far more important. They may be the result of adhesions from burns or wounds, compression, contusions, strains, cold, trauma; also dental diseases resulting from injuries following extractions, malformation and malposition of the teeth, impacted teeth, fractures of the jaw, nerve tumors and pulp nodules. The teeth, more frequently than any other

tissue of the body, are subject to the many diseases that may be directly or indirectly responsible for a greater number of trifacial neuralgias than all other causes combined. A tooth lesion may involve a nerve, around which there may be the formation of cicatricial tissue, induration of the nerve sheath, or an exostosis of the bony wall surrounding the tooth in question. Not infrequently we encounter teeth which apparently are free from decay, the pulp cavities of which are filled by the formation of either secondary dentine or pulp nodules. These nodules or calcific matter exert pressure upon the nerve filaments and are oftentimes responsible for the paroxysms of neuralgic pain. Though the tooth or teeth in question may have been removed, the pathological tissue they produced may remain, or develop other conditions which may be the origin of the most severe type of trifacial neuralgia. Thus the unsuspecting surgeon may overlook this area from which a tooth had been extracted, in searching for a cause for the neuralgia. It has been my privilege to have just such cases referred to me for treatment, and after careful study of the histories, clinical symptoms and x-rays, they were diagnosed as trifacial neuralgias. Alveolectomies were performed for these patients, resulting in complete relief of their sufferings.

Injuries to the alveolar process resulting from extraction of teeth, in the form of fracture of either the external or internal plates or both, permit spiculæ of bone to remain, which oftentimes reattach themselves to the periosteum of the alveolus, and act as peripheral nerve irritants. Fragments of root very often are forced into the cancelled portion of bone, and may cause pressure upon the nerve, especially in the lower jaw on account of the mandibular canal. Abscesses from unerupted teeth, impacted teeth, and granulomata which are the results of low grade infection of the periodontal membrane, besides being a focus from which toxic absorption takes place, may be the cause of trifacial neuralgia. These usually give no local discomfort, but may cause irritation and inflammation of any or all of the branches of the trifacial or 5th cranial nerve, thereby inducing neuralgia.

Symptoms.—Paroxysms of pain may occur suddenly without any warning. The pain may appear anywhere along the course of the terminal branches of the 5th cranial nerve. If it is situated in the superior maxillary branch, the pain will probably radiate over the cheek-bone, beneath the eye, the alæ of the nose, lips, gums, and teeth of the upper jaw. If it is displayed in the forehead, temple, inner canthus of the eye or the globe itself, the ophthalmic branch is affected. Profusion of tears is produced by involvement of the lacrymal branch. Pain along the mandible or the tongue indicates affection of the 3rd division, and is described as sharp, lancing, stinging, and intermittent, increasing in violence until a climax is reached after which it subsides abruptly only to recur after a short duration of rest, or to remain quiescent until a future attack.

The pain in trifacial neuralgia may originate from one or more centers. It does not occur at regular intervals, and as the period of rest lengthens, the patient is led to believe that there will not be a recurrence, when suddenly, without any

warning whatsoever, there is a paroxysm of burning, boring, darting pain, which increases in severity and duration. I have seen patients holding their hands to their heads, walking with fear in their eyes, saliva drooling from the corners of their mouths, and almost unable to speak due to the intensity of their pain. Under the stress of such violent pain patients have been known to tear the hair from their scalp. I have seen paroxysms of pain induced by the slightest touch to the lips or cheek, or even by currents of air. The pupil of the eye of the affected side may be slightly contracted accompanied by such other manifestations as conjunctivitis and photophobia. Flushing of the face is also a prominent symptom. Not infrequently do we find hysteria a most confusing companion to trifacial neuralgia. Patients seeking relief from this terrible malady have subjected themselves to all sorts of medicinal and surgical treatment without any apparent success.

Diagnosis.—As in all other abnormalities, the most important consideration is an accurate diagnosis. A most painstaking search for the general as well as local causes should be made. The taking of the patient's history must be accomplished in a most careful and exacting manner. The patient should be questioned as to his occupation, environment, whether or not he was exposed to poisons, whether or not he had any disease which might have lowered his vitality. He should be further questioned as to whether he was injured or had any dental irritations; what the condition of his teeth were prior to their extraction, the manner in which they were removed, and what if any post-operative treatment was received. The diagnosis can be arrived at only by eliminating one possible cause after the other. The use of the x-ray is quite important. Radiographs should be taken to eliminate the presence of unerupted, impacted, or supernumerary teeth, broken off roots, or odontomas in remote parts of the maxilla or mandible. The presence of chronic abscesses (granulomata) in edentulous mouths is rarely if ever detected in radiographs. The knowledge of their retention in the jaw bones in some cases may be obtained by searching the patient's history. It is my opinion that a large number of cases of trifacial neuralgia result from diseases teeth which leave definite areas of infection in the cancellous portion of the jaw bones in relation to the teeth involved, or which when extracted permit the alveolus to remain jagged. In some instances these areas may be ascertained by careful digital exploration. If the exact area is palpated there is often produced a distinct paroxysm of pain. An x-ray examination of such areas may sometimes prove of value.

The writer believes that the majority of cases of trifacial neuralgia are of local origin, and that most often the local cause is not discovered or removed. He is also fully aware of the fact that certain types of trifacial neuralgias may have their origin in parts of the body quite remote from the seat of pain and it is not his intent to include such cases within the scope of this paper.

Treatment.—Medication is usually first resorted to for the purpose of arresting the pain. The use of anodynes or narcotics may afford the patient temporary relief, but their use should not be con-

tinued over a long period for fear of establishing the drug habit. Such local remedy as crystallized menthol dissolved in alcohol and then diluted about one-half with water has been recommended. Several thicknesses of flannel saturated with this solution and applied over the region of the pain may afford the patient some slight relief.

In spite of the many measures, conservative or heroic, that may be employed to relieve the pain of trifacial neuralgia, the condition will either persist or recur unless the cause is removed. I have seen numerous cases of neuralgia in which alcohol had been injected, but instead of affording the patient relief, the condition seemed to have been aggravated by such procedure. A temporary maniacal condition oftentimes was produced almost immediately following the injection. In some cases of recent origin, the patient would be afforded relief following alcohol injections, but it was of only a temporary nature. On the return of the paroxysms the pain would usually be more intense, more severe, and last longer. Pitres and Vaillard, in 1887, and Schüssler, in 1900, undertook a series of experiments with alcohol injections, and the latter perfected a method of injecting alcohol within the substance of the Gasserian ganglion, with excellent results. In Schüssler's analysis of 209 cases, 123 had injections in the trigeminus. Recurrences, on an average of ten month intervals, were noted in the large majority of cases. Oswalt claimed better results from his injections, saying that 90 per cent. may be benefited, relapses occurring within 5 months in 30 per cent. of his cases. Numerous modifications of the above experiments have been devised, all of which have been found wanting.

For many years division of individual branches of the 5th cranial nerve has been practised for the relief of neuralgia and while such operations may give relief for some months or possibly years, they are not positively curative; such procedure may be warranted when the case, having failed after undergoing conservative treatment, becomes chronic, and the neuralgia is limited to a single branch of the nerve. In the majority of cases, however, the neuralgia eventually extends to other branches and in such cases the more radical operation advised by Krause and Hartley, which consists of the removal of the Gasserian ganglion, may be performed.

The most difficult cases for diagnosis and treatment are those presenting edentulous mouths. In the first place, if anything like an approach to an accurate diagnosis is to be attempted a special set of radiograms that will distinguish the cancellous from the soft tissues is essential. Aside from the fact that one may see in these radiograms cysts, fragments of roots, and granulomata, it is the shadows of the sharp fragments or irregularities of bone (productive of the severe paroxysms in trifacial neuralgias) that are difficult of interpretation. Pathological involvement may be so extensive as to make differentiation of the various tissues extremely difficult, particularly in those cases in which radiographs and histories regarding previous extractions are not available. In such cases a great deal is dependent upon the clinical picture that the patient presents together with the results obtained by careful palpation. Should the patient be wearing dentures, the articulation should be

carefully studied for possible traumatic influences.

The most important step in the treatment of trifacial neuralgia is the discovery and early removal of such local causes as foreign bodies, pressure of bone, irritation of teeth whether from disease, malposition, or impaction, improper adjustment of artificial dentures, scar tissue, callus, adhesions, exostosis of bone, and crowded dental arches. In the attempt at the removal of any of these causes, either by extraction of teeth or by any other surgical procedure, as a result of faulty technique, the alveolus may have been permitted to remain in a jagged condition over which the mucoperiosteum has healed. This irregular state of the alveolus, over which the normal mucoperiosteum is drawn taut, will then act as a local irritant to these already hyper-stimulated peripheral nerve-endings. The correction of this condition can be effected by the operation known as Alveolectomy.

Instrumentarium.—The selection of the proper instruments to perform the operation of alveolectomy with ease and speed is quite important. To some extent it may be a matter of personal equation, but the writer's clinical experience warrants the recommendation of the following instruments for this procedure: (1) Fischer hypodermic syringe with proper needles for the administration of novocain conduction anesthesia; or if (2) general anesthesia is preferred, an anesthetist with the proper outfit for the administration of ether by nasal insufflation; (3) numerous wooden applicators with sterile cotton twisted on one end; (4) cheek retractors; (5) gum retractors; (6) sharp scalpel; (7) periosteal separator; (8) curved scissors; (9) blunt bone chisel; (10) nickel weighted mallet; (11) curets of various sizes; (12) hemostats (mosquito); (13) thumb forceps, several pair; (14) Rongeur forceps; (15) alveolar plane; (16) full curved suture needles; (17) needle holders; (18) black suture silk, No. 6; (19) normal saline solution; (20) novocain-suprarenine tablets E.; (21) tincture of iodine $3\frac{1}{2}$ per cent.; (22) plain sterile gauze.

Operations about the face and jaws should be performed under as rigid aseptic conditions as possible. While extra-oral operations may be performed under strict surgical asepsis, nevertheless such is not possible within the mouth. It should be the surgeon's aim, however, to obtain the strictest asepsis possible in the oral cavity by removing old broken-down teeth, root fragments, tartar, etc., and by the use of a mild, bland antiseptic mouth wash. Before proceeding to operate, the region of incision is swabbed with a $3\frac{1}{2}$ per cent. solution of tincture of iodine.

The hands of the operator and his assistants are sterilized by scrubbing for 10 minutes, using tincture of green soap followed by alcohol and a bichloride solution. It is hardly necessary to add that the instruments, towels, and in fact everything that comes in contact with the wound must be sterile.

Anesthesia.—Perfect anesthesia is absolutely essential to successfully carry out the technique of alveolectomy. Either general or conduction anesthesia may be employed.

The general anesthetics in common use are: ether, chloroform, and nitrous oxide. The choice

of an anesthetic depends upon several factors, such as the length of anesthesia required, region and nature of operation, and the condition of the patient. For prolonged anesthesia, ether and chloroform are the anesthetics of choice. For the vast majority of cases ether should be selected, as it is very much less dangerous than chloroform.

Before the administration of ether for complete anesthesia the following precautions should be observed. No food should be taken by the patient for several hours before its administration, the bowels should be properly evacuated prior to operation and the patient's heart, lungs, and kidneys should be carefully examined. Before administration loose artificial dentures should be removed from the mouth, clothing about the chest and neck must be loosened. The horizontal position is preferred in the administration of the anesthetic, but the patient may be placed in a more convenient position for operation later on. All general anesthetics should be administered by one properly trained for this purpose, preferably an expert anesthetist. The best way of administering ether is by the method known as nasal insufflation. This method facilitates matters for the successful performance of all oral operations.

The clinical experience of the writer is that conduction anesthesia undoubtedly gives the best results. It is imperative that the operation be performed painlessly, therefore, any reasonable method which accomplishes the desired result is suitable. If correct technique of conduction anesthesia is followed the patient experiences no pain whatever. *In operating in the upper anterior region it is essential to give the naso-infraorbital injection on both sides on account of the intermingling of the peripheral branches of the anterior nasal and superior maxillary divisions of the 5th cranial nerve. This injection is my modification of the infraorbital injection taught heretofore.*

Technique of Naso-infraorbital Injection.—The inferior border of the orbit below which the anterior orifice of the infraorbital foramen is situated is palpated, and the tissue overlying the foramen is compressed with the index finger of the left hand, the lip at the same time being drawn upward and away from the gum with the thumb of the same hand. The infraorbital foramen is found 0.5 cm. below the lower border of the orbit and almost exactly above the first bicuspid tooth. The needle is inserted in the reflection of the mucous membrane between the root apices of the canine and first bicuspid. The needle being parallel with the long axis of the canine tooth is advanced obliquely upward and slightly backward at which site the major part of the solution is injected, retaining about $\frac{1}{2}$ c.c. of the solution in the barrel of the syringe. The needle is then deflected slightly upward from the original point of insinuation and almost on a parallel line with the infraorbital ridge, the point of the needle being advanced towards the nasal ala on that side and the rest of the solution in the barrel of the syringe being deposited there. Complete anesthesia with a blanching of the nasal epidermis will be perceived almost immediately after injection. This is verified by the usual exclamation from the patient that he cannot breathe through the nose on the side injected. The patient

should then be assured that breathing has not been impaired but that he is exhibiting the effects of this form of anesthesia. Thus perfect anesthetization of the entire infraorbital region is obtained. Two c.c. of a 2 per cent. solution of novocain suprarenine is all that is ordinarily required for a single injection. The anterior superior lingual area is anesthetized by an injection into the anterior palatine foramen which may be reached by inserting the needle into the posterior border of the large papilla situated in the median line immediately behind the upper central incisors. Anesthesia of the posterior portion of the maxilla may be obtained by the so-called tuberosity injection which is given in the reflection of the mucous membrane above the apices of the second upper molar tooth and behind the molar process. The needle is advanced upward, backward, and inward until about $\frac{3}{4}$ of an inch has disappeared in the soft tissues. The posterior palatal anesthesia is given by inserting the needle into the depression found in the mucous membrane at about the apex of the lingual root of the second upper molar tooth.

Anesthesia of one or both sides of the mandible may be obtained as follows: the tip of the index finger of the left hand is carried along the posterior portion of the body of the mandible following the course of the external oblique line, to a point on the ascending ramus at which the external and internal oblique lines meet. Between these lines is found the retromolar fossa or triangle into which the tip of the index finger is pressed. With the finger in position the needle is then introduced into the tissue about 1 cm. above the level of the masticating surfaces of the lower molars advancing it posteriorly along the lingual side of the ramus for about $1\frac{1}{2}$ -2 cm. at which site 2 c.c. of novocain-suprarenine is deposited.

The time necessary to elapse between the injection and the first incision varies from ten to twenty minutes for tuberosity and infraorbital injections, and one-half hour for mandibular injections. Beginning the operation too soon before anesthetization is complete causes the patient to suffer much discomfort and pain. It is unnecessary to hasten the first incision, since the anesthesia will last from forty-five minutes to one hour.

Technique of the Operation.—The operation known as alveolectomy was originally designed in 1905 by Dr. William L. Shearer of Omaha, Nebraska, for the preparation of mouths for the wearing of artificial dentures; in other words for cosmetic purposes. Since then there have been many modifications of this operation, one of which was the smoothing off of the remaining alveolus by means of carbundum stones used in conjunction with the dental engine. This modification does not appeal to the writer as being good surgical procedure.

The writer, after having performed many such operations either for cosmetic purposes or in the treatment of trifacial neuralgias of local origin, designed a plane for the smoothing off of bone in order to satisfy that step in the technique. This alveolar plane, the name given the instrument, consists of a handle and shank, such as is used for curets, with the plane extending from it at an angle of about 135 degrees. The plane has a flat surface

with cross cut serrations on it, and measures $\frac{1}{2}$ -inch by 1 inch over all. It is operated by a pull and push motion and may be adapted for any portion of the maxilla or mandible; it is hoped that the instrument will be found useful to those engaged in this class of surgery. It is not patented and is cheerfully given to the profession for what it is worth.

The patient is prepared for the operation by having the head and eyes covered by sterile towels and the operating apron adjusted. A $3\frac{1}{2}$ per cent. solution of tincture of iodine is applied to the mucous membrane around the field of operation. The lips, for operations in the anterior portion of the mouth, or the cheeks, for operations in the posterior part of the oral cavity, are retracted, the saliva ejector is placed in the patient's mouth, and sterile gauze pads are placed around the field of operation. After one has carefully observed the area requiring operation, the necessary incisions are made. Anterior to the second bicuspid two deep vertical incisions are made through the buccal mucoperiosteum to the bone, one on either side of the region in question, which are joined by a horizontal incision along the crest of the alveolus. Posterior to the second bicuspid only one deep vertical incision is made through the buccal mucoperiosteum to the bone, which meets a horizontal incision along the crest of the alveolus and is extended beyond the third molar.

The periosteal separator is now used to disengage the entire flap, thus formed, from the bone. Old cicatricial tissue often causes difficulties in loosening this flap from its bony adhesions. This flap, after being raised, is held back by an assistant using the gum retractor for that purpose. The assistant should be prepared to swab rapidly all blood flowing from the exposed region. In many instances these regions are found to be quite vascular and the surgeon may encounter, while operating, several spurts of blood from severed arterioles found in the cancellous bone. These spurts may be controlled by the use of a blunt chisel and mallet, tapping against the exact site from which the blood is pouring forth.

The amount of bone to be removed may be predetermined, the surgeon being guided by the radiographs and experience. This may be accomplished by the use of the rongeur forceps. Very often the surgeon may be forced to change his plan during the operation, due to the fact that the pathological areas or irregular alveolus when exposed is much larger and more complex than revealed by the radiographs. The bone must now be made smooth, leaving no jagged edges, if rapid healing and relief from pain are to be expected. This is accomplished by the use of the alveolar plane devised by me, which is operated by a push and pull movement without creating any heat or maceration of the soft tissues. After having properly rounded and smoothed the bone, the debris is carefully washed away with warm normal saline solution, the area dried with sterile gauze, inspected and palpated.

The successful termination of this operation is dependent upon the painstaking removal of all pathological and jagged bone tissue from the alveolus. The retractors are removed, the area painted with a $3\frac{1}{2}$ per cent. solution of tincture of iodine and

the wound closed by suturing the flap, using black suture silk No. 6 for that purpose. In suturing care should be exerted to engage the periosteum with sufficient tissue to prevent rupturing of the sutures and not to draw them too tightly.

Postoperative Treatment.—The patient is advised to use a mouth wash of boric acid solution with witch-hazel every three hours, which seems to give excellent results. In cases of postoperative edema the patient is advised to apply an ice bag to the swollen face for five minutes every half hour for twenty-four hours. If postoperative pain is severe the patient may be given a powder or capsule containing

R Aspirin gr. x.

Codeine sulph. gr. ¼

Proper evacuation of the bowels is highly desirable to overcome possible autointoxication.

Daily applications of a 3½ per cent. solution of tincture of iodine are made for seven consecutive days. On the seventh day the sutures may be removed, using a pair of thumb forceps, sharp scissors, and cheek retractor for this purpose.

The following case histories have been selected from a large number and are quite characteristic:

CASE I.—Mr. H. F., age 34, occupation, operator on cloaks and suits. Nine months ago patient while engaged in work felt a sudden attack of pain in the right upper jaw involving ear, eye, and upper lip on that side. He endured his pain for a few days, thinking that it was only a cold, but on realizing that his condition was growing worse, he went to his physician and received treatment. After several weeks of treatment the pain persisting the patient was advised to see a dentist, who decided that the pain was due to a bridge that the patient was wearing in the upper jaw on that side. The bridge and teeth to which it was attached were removed, after which the patient felt relieved. A few weeks thereafter the pain returned, only this time more severe than before and the patient repaired to his dentist for relief. Tooth after tooth was extracted with the condition only growing worse. A slight gust of cold air against that side of the face or coming into the mouth produced severe paroxysms of pain. The slightest touch on the affected side, with anything, regardless of how soft or soothing it might be, induced a paroxysm. Walking was painful and the patient was forced to cease his work and for about eighteen weeks suffered from these agonizing pains. He had visited neurological and surgical clinics without any apparent relief.

Family history, negative.

The x-ray examination showed a suspicious condition of the alveolus in the region of the second and third right upper molars.

Wassermann test was negative.

All teeth up to the lateral incisor in the right upper jaw were missing and the gum was apparently normal. Palpation of the edentulous portion revealed slight elevation in the region of the second and third right upper molars.

Alveolectomy was performed April, 1919. The patient was discharged in May, 1919, devoid of pain and feeling well. He returned in October, 1919, as per instructions and reported feeling fine and has not had a pain or an ache since his discharge.

CASE II.—Mrs. C. O'R., age 49, occupation, housewife. Up to about four years ago the patient had worn a partial upper rubber plate which was supported by clasps around the left upper canine and bicuspid teeth. These teeth, for some reason or other were extracted and after the part had healed a full upper denture was constructed for her. Her suffering commenced from the day this full upper denture was inserted into her mouth, beginning with sharp pains in the canine and bicuspid region. She called the dentist's attention to this condition and he exerted every effort to remove the cause by continually filing off the plate. This pro-

cedure gave no relief and the patient ceased going to the dentist. She found that by keeping the plate out of her mouth great relief was afforded her. However, she gradually became accustomed to wearing the plate regardless of the suffering it caused and finally noticed that the left eye was the seat of occasional pain. She consulted an eye specialist under whose treatment she had been for quite some time. The pain in the eye seemed to be growing worse and was accompanied by a twitching of the palpebral muscles. She finally decided to try clinic treatment and after three years of suffering with the eye very much aggravated, came to the department of Oral Surgery for relief.

Family history, negative; Wassermann test, negative; x-ray examination, negative.

The upper jaw was edentulous, and palpation revealed suspicious area in the left upper canine region.

Lower jaw, all teeth present with the exception of the left lower first molar, right second bicuspid, and first molar. Gingiva, apparently normal looking.

Alveolectomy was performed in February, 1920, and the patient was discharged in the early part of March, 1920, with a total subsidence of her pain and a cessation of the twitching of the palpebral muscles. I have seen the patient several times since and she is enjoying the greatest amount of comfort.

CASE III.—Mrs. M. G., age 46, occupation, millinery business. Five years ago the patient complained of pain in the right maxillary region. She visited a dentist who deemed it advisable to extract the right upper second bicuspid, first and second molars. After the extraction of the teeth in question a stationary bridge was constructed and inserted in this region. After being discharged, she experienced periodic attacks of pain. This condition continued for about five years when during the month of June, 1918, she experienced violent attacks of pain in both the maxilla and mandible on that side. The pain was so very severe and intense that she found it impossible to place her head on a pillow without having her husband place the palm of his hand against the occiput and gradually lower her head to rest. Chills and fever accompanied this condition with a drooling of saliva from the corners of her mouth. Turkish towels were placed under the side of the face of the patient while in a recumbent position to absorb the saliva, so great was the pyralism. She felt as if her eyes were growing weaker and weaker. Walking or talking would induce paroxysms of pain which made it necessary for her to support the chin constantly in the palm of her hand. The slightest touch to the lip, cheek, or jaw would induce a paroxysm of pain. She visited a dentist during July, 1918, for relief and he found it necessary to grind into the first lower molar. This tooth after having received quite some treatment, was extracted as well as the bicuspid next to it. The pain after extraction was so severe that the patient was forced to remain in bed for some time, a physician being in constant attendance. When her condition warranted, she was advised to go to an exodontist. Curetage of the bone sockets of the right lower first molar and second bicuspid was performed by the exodontist which gave the patient relief for a few weeks, after which the condition recurred.

The mouth revealed a stationary bridge in the right upper maxilla supported by gold crowns on the first bicuspid and third molars. This bridge with the abutments was quite loose. In the lower jaw the first and second bicuspids and first and third molars were missing. Gingiva apparently normal looking.

Wassermann test, negative. An x-ray examination of the upper jaw showed areas of rarefaction attending the roots and apices of the right first bicuspid and third molar, the crest of the alveolus between being very jagged; the lower jaw showed retained fragment of the root in the first bicuspid region and a pulp nodule in the lower second molar.

After numerous operations, including an alveolectomy, for the removal of the various etiological factors, the patient slowly regained her health with a complete elimination of the pains. This patient has been seen by me for fully one year after the last operation and her condition remains unchanged. She is enjoying the best of health and comfort.

CASE IV.—Mrs. M. G., age 50, occupation, housewife. One year ago patient was nursing her son who was con-

fined to bed with an influenza pneumonia. The son lived in New Jersey at that time thereby necessitating the patient to travel from New York every night, and she would leave for her home early in the morning between the hours of four and five A. M. One month after her son's death the patient was attacked with a sudden paroxysm of pain in the region of the right zygoma. On attempting to open her mouth, the pain was so severe and intense as to make closing of the mouth very difficult. She endured this pain and after six months visited a dentist who had extracted five teeth in the upper jaw on that side in an attempt to relieve her of this pain. The pain grew worse after extraction. She then visited a hospital clinic and was informed that she would have to be operated on to which she submitted very willingly. The patient does not know the exact nature of the operation but claims to have felt better for a short while thereafter. The pain recurred, being more intense and severe, and she decided to return to her dentist who extracted six teeth in the lower jaw on that side. Since these last extractions, her condition has become intolerable making it almost impossible for the patient to speak at times. When the paroxysms of pain come on they are so severe and intense as to cause the patient to pace up and down the floor screaming at the top of her voice. These pains recur on the average of about every twenty minutes causing a twitching of the facial muscles on that side. Walking induces paroxysms of pain with this twitching, and while this condition prevails the patient cannot touch the lower lip.

Past history negative. Wassermann test negative. Family history: Parents died of old age.

Palpation of the edentulous portion of the upper jaw on the right side reveals a jagged condition of the alveolus beneath the mucoperiosteum. The same condition exists in the lower jaw which is also edentulous on that side in the region of the canine and bicuspsids.

Alveolectomy was performed for the patient and recovery followed almost immediately thereafter. There has been a complete cessation of pain and after six months of watching her condition remains the same.

Conclusions.—1. Diseased teeth may be directly or indirectly responsible for a greater number of trifacial neuralgias than all other causes combined.

2. The regions from which these teeth have been extracted may retain pathological tissue or the alveolus may have been injured to such an extent as to have caused a jagged condition thereof, over which the mucoperiosteum has healed.

3. These conditions then act as local irritants to the already hyperstimulated peripheral nerve-endings.

4. Heretofore, the treatment of trifacial neuralgias has consisted of such conservative methods as medication, and alcohol injections, or the more radical procedure in chronic cases, as neurotomy and possibly gasserectomy. These procedures have been considered as symptomatic treatment.

5. Alveolectomy is the surgical procedure proven to be of great value in the treatment of trifacial neuralgias of local origin, causing complete cessation of the severe paroxysms.

25 FIFTH AVENUE.

Diagnosis of Chronic Farcy.—A cab driver was attacked by erysipelas about the elbow joint, following a contusion which did not break the skin. An abscess formed and was followed by other periarticular phlegmons. The pus contained none of the familiar germs. The diagnosis was cryptogenic sepsis, although hemoculture was also negative. Light was thrown on the case when two horses in his stable were found to have acute glanders. A positive seroreaction was now obtained in the patient. The brother of the latter about this time died of an acute malady recognized at autopsy as farcy. The infection of the first patient was finally traced back many months and the disease had pursued a singularly mild course.—*Wiener klin. Wochenschrift.*

RELATION OF PULMONARY INFECTIONS TO THE CALCIUM METABOLISM: SUGGESTIONS FOR A NEW METHOD OF TREATMENT.

By G. DELGADO PALACIOS, M.D.,

CARACAS, VENEZUELA.

WHETHER man has completely lost the instinct, possessed notably by the lower animals, given by nature to guide him in the proper selection of his foodstuffs, or whether this kind of instinct has never existed for him, the fact remains that the immense majority of people and a great majority of physicians do not know that an exclusive, or almost exclusive cow's milk diet is a very harmful dietary, a sort of physiological absurdity.

A simple statement of facts, however, can establish the truth of this proposition.

Milk, by its composition and purpose in nature, is a food intended to supply the mineral as well as the organic necessities of the newly born and growing animal. The quantity of calcium in cow's milk, especially, is far in excess of the physiological needs of adult metabolism. A brief table of foodstuffs, following, shows the relative amounts of calcium in cow's milk and other foods.

According to Bunge¹ foodstuffs are classified in the order of their increasing calcium content for 1000 grams of dry solids as follows:

	Grams		Grams
Sugar	0.000	White of eggs.....	1.30
Honey	0.067	Green peas	1.37
Rice	0.12 to 1.70	Oatmeal	1.42
Brown bread.....	0.26	Prunes	1.66
Beef	0.29	Mother's milk.....	2.43
Wheat bread.....	0.46	Egg yolks.....	3.50
Grapes	0.50	Figs	4.00
Graham bread.....	0.77	Butter	4.11
Pears	0.95	Strawberries.....	4.53
Potatoes	1.00	Cow's milk	15.10
Dates	1.03	Spinach	19.50

It is obvious from the above table, which is presented in some detail on account of the dietary discussion to follow, that cow's milk contains a far greater calcium content than any of the common foods in regular use. Now it will be seen, in the subsequent discussion, that in an individual who partakes of an exclusive cow's milk diet, or of a diet in which cow's milk is the dominant item, a striking phenomenon in the calcium metabolism of the organism of such an individual can be demonstrated.

In the case of an individual fed upon a mixed diet in which cow's milk is minimized, it will be found, in an adult, that, if the intake of calcium present in the mixed foodstuffs is estimated, and a careful determination of the excretion of calcium in the urine and feces is made, both quantities are equal. That is to say, in such a case there exists an equilibrium or balance between calcium intake and excretion.

On the other hand, as soon as an adult individual gives up the natural feeding of mixed foodstuffs and follows an exclusive milk diet or one in which milk is dominant, the same chemical experiment demonstrates the fact that a considerable amount of calcium is retained in the body.

T. Rumpf² was the first investigator who detected this fact: some months later Hirschler and Terray³ verified calcium retention during a milk diet by means of exact and extensive balances of nutrition. F. Ofringa⁴ has also made nutritional in-

vestigations upon individuals during a diet in which milk was dominant and, in addition, a diet to which calcium salts were added.

The author of this paper,* during investigations seeking to establish the cause of this lime retention in the human body, by varying the milk diet was successful in demonstrating the cause and control of certain of the points in question.

In his experiments, during the first period the diet was almost exclusively composed of cow's milk. In the second period a similar diet was followed, but was more abundant, and allowed more water, together with cellulose and lime juice which were added to increase the volume of the feces and the urine.

The comparative results of these two series of experimentations follow:

First Period—Milk Diet—Six Days

	CaO
Calcium intake with milk, food and beverages.....	11.439
Output by urine.....	0.862
Output by feces.....	10.242
Calcium retention.....	0.335

Second Period—Acid Milk Diet—Six Days

Calcium intake with foodstuffs, milk and beverages..	15.166
Output by urine.....	1.203
Output by feces.....	14.025
Calcium retention.....	0.062

These experiments show that lime retention may be prevented if by some mechanism its elimination by the urine and feces is provided for. But for the moment the opposite fact is the more significant. On a dominant milk diet fecal stagnation usually occurs and this, with the diminution of the urine, is the main cause of calcium retention.

During fecal stagnation intestinal putrefaction is greatly increased and from this cause abnormal amounts of ammoniacal compounds and volatile fatty acids are produced, which attack the abundant calcium carbonate and phosphate of the feces, forming, in this manner, soluble calcium salts of putrefactive origin; that is, in the main, the soluble calcium salts of the volatile fatty acids. These are reabsorbed into the blood, and by a mechanism to be discussed later, are likely to remain there. For a more detailed explanation of this process the reader is referred to another paper of the author,* "The Retrograde Circulation of Calcium in the Human Body."

I do not intend to assert that calcium retention is invariably the result of a heavy milk diet, for, as I have shown, if this diet is modified with the admixture of other foodstuffs, especially fruits rich in vegetable acids and cellulose, elimination of lime is provided for, and little retention is a consequence. On the other hand, other foodstuffs rich in calcium, under conditions of fecal stagnation may bring forth the phenomenon of calcium retention.

It is interesting to note that for lime retention it is not necessary that the individual be an adult, for a human baby can charge its body with calcium if mother's milk is substituted by cow's milk. The enormous difference between the amounts of lime in the two milks explains the retention. Blaubeurg⁷ determined that in infants, during a course of nursing on mother's milk, the relation between the amounts of excreted urinary and fecal calcium was 76:24, that is to say, the adult ratio is inverted in infants. When infants were fed upon cow's milk, however, the relation was similar to that for adults and varied from 45:55 to 22:78.

A very important point to mention is that in nursing babies the reaction of the feces is normally acid (lactic acid); in adults and infants fed upon cow's milk the reaction is usually neutral or alkaline (volatile fatty acids). The fact is, that when nursing infants are changed to a diet of cow's milk, diluted or undiluted, remarkable amounts of lime salts accumulate within the body, very probably, as has been suggested, by retrograde fecal absorption.

From what has been explained, one must not consider calcium as a poisonous element, and that the elimination of calcium in an adult assures health. As a matter of fact, a certain amount of calcium is necessary for the proper function of the tissues, organs, and the whole economy. Certain authors estimate that 1.5 grams of calcium oxide is a sufficient amount to fulfill this purpose every twenty-four hours.

In addition to its direct action as calcium ions on metabolism, this element is an excellent antitoxic base, making insoluble many known and unknown poisonous organic compounds produced during intestinal digestion, fermentation, and putrefaction.

But when these latter phenomena are abnormal, and there is a long-lasting fecal stagnation, and lime salts are abundant, then an active fecal reabsorption of poisonous compounds into the blood takes place. The result of this process is an intense predisposition to certain diseases or actual disease resulting therefrom.

For a more extensive study of this subject the reader is referred to the second chapter of the author's book⁸ treating of these topics. It is only necessary to point out here that when this sort of calcium intoxication is taking place—and the author believes, and will offer supporting evidence that this special intoxication is the chemical basis for certain diseases—the fundamental therapeutic indication is to provoke a sharp decalcification of the body by means of prolonged fasting⁹ during which there is a really enormous excretion of lime, with all other poisonous substances.

Influenza and pneumonia, together with other pulmonary infections, are the special diseases that the author believes have a chemical basis in abnormal calcium retention. In short, what has been called empirically until now "a peculiar predisposition to suffer from croupous pneumonia," and similar statements, is, actually, a predisposition resulting from calcium retention.

The reasons for this statement follow:

1. *Calcium salts are necessary for the production of fibrin.* Although the phenomena of blood-clotting has been studied many years by various investigators, the biochemical problem is very far from its complete solution. But it is a well-established fact that calcium is an element absolutely essential in the process whereby fibrinogen is converted into fibrin. Blood from which calcium has been precipitated will not clot, and the addition of calcium salts promptly causes it to do so. Presumably, provided all other chemical and pathological conditions are favorable, the more abundant is the supply of available calcium salts, the richer the production of fibrin.

2. *In such conditions as lobar pneumonia (croup-*

ous or fibrinous pneumonia, lung fever) the phenomena of the disease include an abundant production of fibrin, which appears in the lungs, in the blood, in the organs and excretions.

"During red hepatization lung tissue is solid, firm, airless. One of the most remarkable features is the friability, in striking contrast with the healthy lung, which is torn with difficulty. The surface has a granular appearance due to the fibrinous plugs filling the air cells. The smaller bronchi often contain fibrinous plugs. Microscopically the air-cells are seen to be occupied by coagulated fibrin, in the meshes of which are red-blood corpuscles, mononuclear and polynuclear leucocytes, and alveolar epithelium."¹⁰

"In typical cases of croupous pneumonia almost without exception the Frankel Weichselbaum pneumococci will be found, and eventually the Friedlaender pneumobacilli, both germ producers of the disease. By employing the coloration method of Weigert for fibrin, it is possible to show them in the fibrin shreds."¹¹

"A striking feature of the blood slide is the richness and density of the fibrin network. This corresponds to the great increase in fibrin elements, the proportion rising from 4 to 5 parts per thousand. The blood-platelets are greatly increased."¹²

"Pfeiffer determined the fibrin content of blood in diseases and found it increased in diseases with leucocytosis (pneumonia, rheumatism, erysipelas, scarlet fever) except leukemia, where it was normal; in diseases without leucocytosis (typhoid, malaria, nephritis) the fibrin was normal in amount. Stassano and Billon have furthermore shown that the amount of fibrin ferment varies directly with the number of leucocytes in the blood. In experimental infections in animals Langstein and Mayer found a specific increase in pneumonia sepsis, which bears undoubtedly an important relation both to the characteristic fibrinous nature of the exudate in pneumonia and the striking amount of fibrin in pneumococcus pleuritis, peritonitis, etc."¹³

"The latter authors consider the increase of fibrin also a specific property of the pneumonia germ, and to corroborate their opinion that the greatest fibrin exudation they have observed was found in cases of peritonitis produced by pneumococci."¹⁴

Loeper and Béchamp,¹⁵ who have studied especially the lime retention during disease, say that in the course of certain diseases, although a rich feeding in lime is given, the lime diminishes considerably in the urine and feces, suggesting an internal retention in the tissues. The following interesting figures are quoted from their paper:

	Weight of the Lime in the Diet Grams	Total CaO Excreted
Acute tuberculosis	1,200	0.165
Cavernous tuberculosis	1,500	0.22
Pneumonia	1,400	0.25
Congested lung	700	0.07
	CaO in 1,000 Grams Dry Solid	
Pneumonic sputum	0.45	
Bronchopneumonic sputum	0.50	
Bronchopneumonic sputum	0.70	
Asthmatic bronchitic sputum	0.26	
Simple bronchitic sputum	0.24	
Pneumonic heart	0.47	
Normal heart	0.29	

The efforts of the human organism to clear itself

of these abnormal and pathological retentions of lime lead to the formation of insoluble organic compounds (fibrin and other proteins) which obstruct the air passages, and these insoluble compounds are finally removed only by a slow process of autolysis, effected by digestive and leucocytic enzymes.

As a final deduction from what has been established, the radical indication to prevent or to cure pneumonia, influenzal or otherwise, is, as the author's experience has taught, to provoke a rapid decalcification from the body of abnormal lime retention.

This can be done, as has been suggested and established by the author's clinical experience, by:

1. Suppression of milk and other dairy products during the disease and convalescence.
2. Repeated purgatives, at least one every day. The selected purgative has been castor oil, which has been employed until all the fever is gone, the tongue clean, and the appetite reestablished.
3. Prolonged fasting until the same phenomena of returning health are well established.
4. Plenty of pure filtered, or thoroughly boiled water. In order that the water be entirely lime-free, distilled water is preferred above all other.

To this system may be added, when deemed necessary, the indicated drugs to moderate fever or remove pain.

The author realizes that this method of treatment will be considered too energetic, but in the light of his own excellent results, it deserves careful consideration, for it must be remembered that pneumonia "is the most widespread and fatal of all acute diseases."

Other methods of treatment, that might be styled milder, cannot be pointed to with much pride when it is remembered that more than 100,000 cases of pneumonia are lost every year in the United States.

The author has had not only a wide experience in practice with the method of treatment outlined above, but also a personal experience. Since the pandemic of 1918 he was attacked twice; afterwards, having applied his method of abortive treatment, at every incident influenza the disease was easily prevented.

During the terrible pandemic of 1918, this method of treatment was employed in an unusually large number of cases by Dr. A. Benchetrit, of Caracas, Venezuela, with almost invariably good results. The mortality in Dr. Benchetrit's series of cases was reduced to less than 0.5 per 100. At the same time in Caracas, the author's son employed the same method. The incidence and mortality in Caracas were appalling. By this method the mortality was vastly reduced.

The Bureau of the Census in Washington says that of 46 large cities in the United States with a total population of 23,000,000, 82,360 deaths occurred from influenza and pneumonia in the period from September 8 to November 9 during the great year of the pandemic. The normal death rate during the same period would be 4,000.

Comparing this with the death rate in Caracas, a city of 100,000 people, during the same period, we find:

100,000 people in American cities during 31 days—339 deaths.

100,000 people in Caracas during 31 days—2,000 deaths.

This figures at about seven times the mortality rate of the American cities and demonstrates the severity of the epidemic in Caracas. With this in mind it is enlightening to observe the mortality figures obtained from recorded cases in which the author's method of treatment was employed.

Dr. A. Benchetrit (and associates): 900 cases in Caracas, three deaths; 600 cases in Maracaibo, no deaths; 2,000 cases in San Fernando de Apure, five deaths.

G. Delgado Palacios, Jr.: 1,800 cases in Caracas, including 112 cases of pneumonia, nine deaths.

Fiat experimentum! and save American lives. Remember that more than 83,000 lives are lost every year in the United States, and that the present guiding medical ideas in the treatment of this infection must be entirely inadequate.

A CONCEPT OF X-RAY PATHOLOGY.

IX.—FRACTURES.

By A. J. PACINI, M.D.

WASHINGTON, D. C.

CHIEF OF X-RAY AND LABORATORY SECTION, HOSPITAL DIVISION,
U. S. PUBLIC HEALTH SERVICE.

THERE are two motives that actuate the x-ray study of fractures: first, to determine the presence or absence of fracture; secondly, if present to determine the degree of deformity. For purposes of x-ray pathology, fractures may be divided into those of flat bones and into those of long bones. Flat bone fractures involve the skull, and, so far as x-ray pathology is concerned, the vertebra.

FRACTURES OF THE SKULL.—In the question of skull fractures, the points to be considered are the character of the fracture in accordance with its lines, such as comminuted, depression, linear, fissure, or with loss of substance; and whether one or both tables are involved.

Linear fractures occasion a radiopaque line if both tables are involved, a radiolucent line if only one table is involved. They may take any linear direction and are to be differentiated from suture lines, diploic vessels and arterial grooves, all of which have different typographic curves and are characterized by smooth edges and greater radiopacity than the average fracture.

Comminuted and stellate fractures are generally obvious. Depressed fractures may be bounded in part by radiopaque margins owing to the increased density incident to the superimposition of the depressed margin on the normal bone.

Basal fractures are frequently overlooked. The technology for eliciting basal fractures should include a vertical projection of the base in addition to an anteroposterior, posteroanterior, sinistrodextral and dextrosinistral view in each case.

VERTEBRAL FRACTURES.—It is rarely possible to elicit fracture lines in the vertebra. Vertebral fractures are recognized in x-ray pathology by the deformity produced in the body of the vertebra. Crush fractures are found most commonly in the thoracic and lumbar regions. In antero-posterior view of the spine they may be entirely overlooked; so that a lateral view should be used in the effort to detect crush fractures.

Pathology involving the fifth lumbar vertebra should be expressed with caution. The fifth lumbar vertebra seems to assume various forms that may represent pathologic states although pathology is actually absent. The vertebra is normally tilted, and as it lies between the ilium wings, a lateral view cannot be obtained. The study of this vertebra should therefore be conducted stereoscopically.

FRACTURES OF EXTREMITIES.—Fractures of the long bones may be divided into two classes: those affecting the diaphysis and others affecting the epiphysis.

In the study of epiphyseal features the roentgenologist should be conversant with the age of fusion of epiphyses. The following table is taken from Holmes and Ruggles who have modeled it after that of Rotch and Morris. In certain cases the results obtained in 30,000 x-ray studies are appended in a separate column.

	Rotch and Morris Age of Appearance	Age of Fusion	Pacini Age of Fusion
Ribs: Epiphyses for head and tubercle	15	23	..
Clavicle: Small epiphysis of the ster- nal end	19	25	25
Epiphysis of acromial end	8 mos.	20	18
Humerus: Head	3	20	20
Greater tuberosity	4	20	20
Lesser tuberosity	4	20	20
(All fuse at six years and join the shaft at twenty years.)			
Capitulum	1	17	18
Internal epicondyle	5	13	13
Trochlea	10	17	17
External epicondyle	12	17	16-17
(The capitulum, trochlea and ex- ternal epicondyle join as a mass at seventeen and the internal epicondyle at eighteen years.)			
Radius: Head	5	17	20
Lower epiphysis	2	20	17-18
Ulna: Olecranon	10	17	17
Lower epiphysis	4	18	18
Upper epiphysis	..	..	18-20
Carpus (In the order of appearance):			
Magnum	1	..	..
Unciform	1-1½	..	..
Cuneiform	2-3	..	..
Semilunar	4-5	..	..
Trapezium	5	..	..
Scaphoid	5-6	..	..
Trapezoid	6-8	..	..
Pisiform	12	..	..
Metacarpals: Epiphyses	3	20	20
Phalanges: Epiphyses	3	18	20
Pelvis (Tubule and ischium unite at eight years; the acetabulum closes at sixteen years):			
Epiphyses for	..	..	25
Crest of ilium	15	20	12
Ischial tuberosity	..	..	..
Anterior inferior iliac spine	..	..	..
Tubercle of pubes	..	..	..
Femur: Head	1	19	18
Greater trochanter	4	18	18
Lesser trochanter	13	17	18
Lower epiphysis	8 mos.	20	..

	Roach and Morris Age of Appearance	Age of Fusion	Pacini Age of Fusion
Patella	2	24	20
Fibula: Upper epiphysis.....	4	24	20
Lower epiphysis.....	2	20	18
Tibia: Upper epiphysis.....	9 mos.	22	18
Lower epiphysis.....	2	18	..
Tarsus (In order of appearance):			
Calcis.....	6 mos.	..	..
Epiphysis of calcis.....	10	..	..
Astragalus.....	7 mos.	..	..
Cuboid.....	9 mos.	..	..
External cuneiform.....	1	..	..
Internal cuneiform.....	3	..	..
Middle cuneiform.....	3	..	..
Scaphoid.....	4	..	..
Metatarsals: Epiphyses.....	3-8	20	..
Phalanges: Epiphyses.....	4-7	18	20
Sesamoids of flexor hallucis brevis.....	5	..	..

Vertebrae: Ossification is from three primary centers, one for the body and one for each lateral mass. The nucleus for the body is often bilobed, with a partial plane of cleavage in the vertical or horizontal diameter. The laminae unite during the first year. Five secondary centers described in the anatomies—namely, thin plates on the upper and lower surfaces of the body and the tips of the mammillary tubercle, transverse and spinous processes—appear at the age of fifteen to twenty years and unite at twenty-five. The fifth lumbar vertebra is an exception in that it ossifies from five centers, one for the body, one on each side from which is developed the superior articular process, pedicle and transverse process, and one on each side which subsequently form the inferior articular process, lamina and spinous process.

Diaphysal Fractures.—A fracture is described as a solution of continuity of a bone. A distinction has been made between fractures and wounds of bones. Fractures may be of all varieties of which two general types are of importance to the x-ray pathologist. These are traumatic fractures and pathologic fractures. Traumatic fractures may assume any form, and depending upon the line of fracture, they may be described as oblique, longitudinal, transverse, spiral, T-shaped, V-shaped, stellate, or irregular; and any of these varieties may be complete, incomplete, greenstick, or fissured. A fracture may be uncomplicated or complicated. The complication may be inflammation, tumors, syphilis, or foreign bodies.

Fracture repair is dependent in a great measure upon the periosteum and upon the presence or absence of complications. If infection is absent there is no tissue necrosis and new bone is produced by all osteogenic structures. When comminution is extensive, new bone generates all around the broken surfaces so that the healed fracture presents a greater area than a simple non-comminuted fracture would present.

Callus formation does not appear to receive the amount of attention that it should. In children the shadow of a beginning radiopaque mass is seen to collect between the fragments of a fracture about the tenth day; in adults the callus is hyalin and radiolucent or radiopaque until it becomes infiltrated with calcium salts, usually at the end of three weeks; in old people calcium infiltration into callus does not usually take place before six weeks, so that no radiopaque callosity is visible before this time.

Calcium infiltration of the callus takes place at the portion nearest the bone and spreads from this point to the periphery of the callus mass. Between the inner boundary of the callus mass and the bone fragment a clear radiopaque stratum is observed. This is the osteogenic space. Calcification may be considered in progress so long as the osteogenic space is visualized; but when it becomes obliterated, calcification may be considered complete. When freshly deposited the calcium offers no regular arrangement in the callus; but under the stress of muscular action, the radiopaque material tends to

adjust itself in an orientation corresponding to that of bone in the immediate vicinity. As the bone markings become characteristic, roughened edges and exuberant boundaries of the callus mass are rounded off.

Non-union may result from an interposition of the soft parts between the fragment surfaces; or it may be the result of a systemic disorder that reflects osteogenic inertia, particularly in cases of syphilis, tabes and acute systemic infections, although, after close investigation, it would seem these causes of non-union have perhaps been overrated. In comminuted fractures non-union rarely occurs.

Muscle Action and Fracture.—It would seem at first entirely superfluous to discuss the topic of fractures for the reason that because of its old existence in x-ray pathology, nothing new or striking might be advanced. Yet, the most essential feature in the study of fractures is often entirely overlooked and is seldom if ever reported by the x-ray pathologist. The conception that it is desired to convey in connection with the x-ray pathology of fractures, affecting of course the long bones, is that of passiveness of the bone in contra-distinction to the activeness of the muscles involved in a fracture.

A fracture of a long bone should be regarded as representative of disturbances in the muscular balance of the surrounding parts; and the deformity incident to a fracture should be reported, not alone in terms of overriding and fragment displacement, but in terms of disturbance in muscle pull with the specific enumeration of the muscle or group of muscles responsible for the deformity.

It is ever to be remembered that long bones are dominated by muscular function; and with the disappearance for the necessity of muscular function the necessity for the bone likewise evanesces. There are numerous examples in comparative biology and anatomy of the subservience of bone to muscle.

The muscle origin represents its fixed point or basis for action and in contradistinction to the insertion of the muscle, the origin generally is nearer the spine axis of the body. Speaking generally the tension is therefore in the direction of the plane from insertion to origin; although many muscles are capable of acting in the reverse way, especially the flexors and extensors of the hip, knee, and elbow.

Muscle Rest.—Muscle is normally possessed of two properties, one of contraction, the other of relaxation. Muscles are generally paired in a manner that the stimulus which causes one set to contract will at the same time cause the alternative set to relax in the opposite direction. When a muscle is contracted or relaxed it is in an irritable state. There is a position intermediate between contraction and relaxation in which irritability is lost. The loss is due to an exact balance of the power of contraction against the power of relaxation; so that the muscle is not in a state of inaction but is in an active state in which its opposite potentialities are exactly balanced. There are two important factors connected with a muscle in this condition. The first factor is mechanical and represents the so-called "zero" position of muscle rest, described by W. C. Mackenzie. In the zero position the muscle pull being exactly neutralized, the bone in

the part will have no pressure exerted on those points of origin or insertion of the muscles at rest. This principle has been used extensively during the war in the treatment of fractures, particularly through the use of traction. The traction accomplishes the dual purpose of overcoming fragment overriding and of maintaining the fragments adequately separated in the position of election, that of muscle rest. If traction is applied in the axis of the muscle rest plane, then the bone ends need no other contrivance to keep them aligned; for in the zero position, all muscular forces being equalized in opposite directions, and therefore neutralized, there is no force to operate in producing bone displacement. The second important factor in connection with the zero position of muscle rest seems to have been overlooked and is equally as important as the first factor. In any position other than muscle rest a muscle will find itself either contracted or relaxed, or, expressed physiologically, the muscle will find itself in a state of continued irritability. Constant irritation causes muscular fatigue, which interferes with the tone of the organ as well as with the nutriment of the muscle. Since the soft parts in a fractured area are to be immobilized, it is obviously imperative that they be placed in the zero position in order to eliminate every possibility of continued irritation; and the zero position accomplishes this desideratum with the additional accomplishment of maintaining the muscle neutral as to irritability but active as to physiology, and therefore conducive to maximum nourishment and physiologic care.

In freshly sustained fractures, therefore, the x-rayist should report pathology not alone in terms of the anatomical part affected, of the variety (simple, sprain, multiple, comminuted, epiphyseal), of the line of fracture (complete, incomplete, greenstick, fissure), of the direction (oblique, longitudinal, transverse, spiral, T-shaped, V-shaped, stellate, irregular), of the degree of fragment displacement (0, 1, 2, 3), of the direction of the upper and lower fragment and of the presence or absence of overlapping; but he should take such views of the fractured part as are necessary in establishing definitely the disturbed balance of muscle group pull responsible for the deformity, with the view to guiding the surgeon in the correct alignment of the part by traction for obtaining the zero position in the correction of the injury sustained.

Fractures of the Humerus.—Fractures of the humerus are divided into those of the anatomical neck, surgical neck, greater and lesser tuberosities, and epiphyseal separations of the shaft, supracondylar, discondylar, condylar, and epicondylar. Involvement of the musculospiral nerve must always be considered in humeral fractures.

Fracture of the anatomical neck shows a varying pathology in which the head may be completely detached from the shaft and rotated about on its axis or even driven through the ruptured capsule into the axilla. The fracture is accompanied by a great extravasation of blood which invades the capsule, and, if unbroken, greatly distends it. This enormous swelling may clinically confuse the surgeon into suspecting dislocation; so that the x-ray will confirm Dugas' test in deciding definitely regarding

the presence or absence of associated discoloration.*

An injury involving the head of the humerus should be rayed at once to establish whether or not impaction is present. If impaction is visualized it should be reported to guide the surgeon in minimizing manipulation.

In those cases in which the head is impacted, or in which minimum separation has occurred, the callus arises mostly from the lower fragment; and in its proliferation there may result a thickening of neck, causing an adherence to the capsule of the formation of exostoses that extend out into the joint structure. There is a possibility that the auxiliary vessels and plexus branches may sometimes become adherent to the callous mass formed in the repair. The x-ray pathology of non-union may be that of necrosis of the head, or of an inability on the part of the metabolism to supply adequate callus.

Fractures of the surgical neck: Fractures of the surgical neck may be oblique, transverse or serrated. The bone breaks below the tuberosities to which the abductor and rotary muscles are attached, so that the head is rotated and abducted, and the shaft is drawn inward by the muscular attachments of the pectoralis (adductor), teres major (extender), and latissimus dorsi (internal rotator) while the biceps, coracobrachialis (bender), and deltoid (abductor) lift the lower fragment. This combination of muscle forces makes for shortening with displacement provided impaction is eliminated. In attempts to reduce the shortening, care must be exercised to avoid danger to the brachial vessels and nerves.

Fractures of the surgical neck of the humerus, in order to produce muscle rest must be treated in extreme abduction and rotation out.

Fractures of the Shaft: These may occur at any point in the continuity. The pathology varies, the line of fracture being oblique, transverse or dovetail. Impaction is rare. The displacement varies with the site of fracture. If the fracture occurs above the insert of the deltoid, upper third of the shaft, the upper fragment is drawn inward by the pectoralis major and the lower fragment is drawn upward and outward by the deltoid; when the fracture occurs below the insertion of the deltoid, as in the middle and lower third, the upper fragment is drawn outward, the lower fragment is drawn inward and upward and is always rotated in, in amount varying between 15 and 90 degrees. Injury to the musculospiral nerve is especially common in fracture of the middle third. In the treatment of fractures of the upper half of the humerus muscle rest is obtained by rotation out and abduction, the rotation and abduction being governed by the site of fracture; whereas, fractures of the lower half do not generally require rotation and abduction. Traction should always be made in the direction of the upper fragment; so that the x-ray report should contain a precise statement of the direction of the upper fragment.

Fractures of the Lower End: In transverse frac-

*Dugas' test consists in the surgeon placing the hand of the injured arm on the opposite shoulder and then pressing the elbow against the chest wall. If the elbow can be pressed against the chest wall, no dislocation is present; if it cannot be done, dislocation is assumed.

tures of the lower end of the humerus the lower fragment is displaced backward. A fracture of the lower end of the humerus should immediately invite an x-ray survey of the elbow, comparing especially the injured with the uninjured side.

There is nothing particularly important incident to the x-ray pathology of fractures of the lower end of the humerus other than definitely to describe the extent of solution of continuity and the presence of fragments and their location. With the forearm in extension, the external and internal condyles, joined by the intercondyloid line, should lie normally nearly level with the upper end of the olecranon. The points can be palpated clinically better than they can be traced on the x-ray plate.

(To be continued.)

APPENDICITIS, AND SOME OF THE DIFFICULTIES ATTENDING ITS DIAGNOSIS.

By A. WIESE HAMMER, M.D.,

PHILADELPHIA, PA.

SURGEON TO THE AMERICAN HOSPITAL FOR DISEASES OF THE STOMACH; INSTRUCTOR IN ANATOMY, GRADUATE SCHOOL OF MEDICINE, UNIVERSITY OF PENNSYLVANIA, POLYCLINIC SECTION; SURGEON TO THE PENNSYLVANIA RAILROAD.

THE statement frequently heard that appendicitis is a disease most easy of recognition, and that failure to correctly diagnose it shows lack of elementary surgical training, is an assertion not proved by clinical annals, nor does it accord with the results of surgical experience. It is an axiomatic saying that the correct interpretation of many affections is the accomplishment of the master, but alas! too often the skilled physician and surgeon in these cases is baffled at arriving at an incontrovertible decision.

It would seem conclusive evidence that the occurrence of many of the cardinal signs of appendicitis in themselves would be sufficient evidence to clinch a diagnosis; but the fallacy of this reasoning becomes apparent as we proceed in the consideration of the subject, and it will appear still more apparent, when we shall have reviewed the various pelvic and abdominal conditions that may simulate appendicitis, that may give rise to an appendicular infection, or that, by extension of the process by contiguity, may bring about appendicitis through some peculiar or unusual etiological factor.

It is a fact conceded by pathologists and by students of topographical anatomy, that in not a few instances contiguous structures may be the seat of, or give rise to, disease which often is not diagnosed as the seat of the disease, but which is referred to a more distant area. In support of this statement attention is directed to the close proximity of the mesoappendix and the ovary, through the interposition of a fold of peritoneum and the coexistence of appendicitis with one of a number of gynecological affections, be it the ovary, the fallopian tubes, the pelvic fascia, etc., or conversely, affections of the latter may give rise to appendical disease, or by reflex action may strongly simulate some diseased state of the vermiform appendix.

Although appendicular involvement is likely to affect any or several of the pelvic or abdominal viscera, strangely enough, the liver is the organ

probably most predisposed to infection. Why this is so, needs explanation. But the fact obtains, nevertheless, that cholecystitis, cholelithiasis, acute suppurative hepatitis, and acute suppurative perihepatitis are not infrequently brought about through infection of the appendix. Again, the results of clinical research abundantly prove that chronic gastric ulcers and chronic duodenal ulcers, may find their etiology in the presence of septic thrombi of appendical origin.

It may seem a long distance from appendicitis to the following tabulated list of affections, but the differentiation between appendicitis and each of these is often a matter of extreme difficulty. These include cholelithiasis, acute intestinal fermentation, renal calculus and retention, acute tubal infection, rupture of an intraabdominal abscess, gastric and intestinal perforation, intussusception, tuberculosis of the ileum, the twisted pedicle of a tumor.

As was intimated before, appendicitis may give rise to symptoms apparently removed from the seat of disease or from the atrium of infection, or infections elsewhere may give rise to reflex symptoms of appendicular involvement, or through continuity or contiguity of structure, pathological processes may be set up.

In illustration of some of these statements, especially relating to the pain referred to the seat of the appendix, the location of the infection being at a remoter area, we mention: atonic dilatation of the stomach, any one of the component parts of so-called splanchnoptosis, inflammation of the omentum, intestinal kinks, etc., where operations so commonly done upon the appendix quite naturally have proved so unavailing.

In locating the seat of the affection in the right iliac fossa, we must differentiate at least eight other diseases that may be found in this important region, and for easy reference we tabulate these as follows: tuberculosis of the cecum, malignant disease of the cecum, a ureteral calculus, psoas abscess, herpes zoster of the eleventh and twelfth intercostal and of the first and second lumbar nerves, typhoid appendicitis, tabes dorsalis, thrombosis of the mesenteric vessels.

It is worthy of note, in passing, that rheumatoid arthritis of the spine is not infrequently confused with cases of appendicitis—the periodic abdominal pain, simulating the suffering in recurrent appendicitis, but the temperature of appendicitis is absent and the rigidity of the right rectus muscle can be made to disappear through the application of persistent manual pressure. This error in diagnosis occurs because the surgeon focuses his attention upon the abdomen and fails to examine the patient's back. Appendicitis must be carefully differentiated from pretaxic pain.

The diagnosis of appendicitis takes on added significance because the appendix so often involves the female genitalia, or *vice versa*. Deaver believes that appendicular affections predispose to infections of the adnexa; the reverse of this opinion is held by other surgeons and by most gynecologists. Deaver believes that a long appendix coming in contact with or in close relation to the pelvic organs may infect them, while Ochsner finds that there may be, and often is, the production of ovarian cysts, the result of an appendicitis. Appendicitis

in early life and at puberty may so involve the female appendages as to eventuate in absolute sterility. Rupture of a tubal or ovarian abscess may give rise to a train of symptoms, indistinguishable from those of appendicitis.

The differentiation of cases of appendicitis in children is always surrounded by difficulty; this may arise from the child being too young to convey its thoughts, or to the lack of intelligent data obtainable from the sufferer or from its parents or care-taker, and also because of the close resemblance of appendicitis to many gastrointestinal affections of the very young. Thus, the symptoms of a gastroenteritis may so resemble an appendicular attack that often, from lack of a true history of the case, the physician is not infrequently misled in his diagnosis. Intussusception, although offering no temperature rise, may be mistaken for appendicitis. Pain in the appendicular region is often complained of in right-sided pneumonia in children; the same is true if there is diaphragmatic involvement in cases of pleurisy. The many abdominal pains complained of by children when the offending process is located elsewhere, caused Trousseau to exclaim: "Whenever an infant complains of pain in the abdomen, carefully examine his chest."

The clinical picture of chronic appendicitis is often so blurred that much confusion attends the diagnostician's attempts to lucidly interpret the meaning of the symptoms. Many of these cases are incorrectly regarded as affections of gastric origin; others diagnose it as one of several intestinal diseases; and because of loss of weight, increased urination, gastrointestinal disorders, etc., many physicians repeatedly examine the urine and are perplexed at not finding sugar as a reward for their efforts, and seek an explanation of its absence in some fault in their laboratory technique.

One thought seems worthy of emphasis. Tenderness cannot always be elicited, by the usual method of palpitation, at the exact spot where the appendix is supposed to be normally located. When there is difficulty in detecting the exact seat of the painful area, resort should be made to examination by the rectum and the vagina. In chronic cases and in those instances where the appendix comes off from the cecum posteriorly, rectal examination is of paramount importance.

As was remarked in the introduction of this brief article, "the statement frequently heard that appendicitis is a disease most easy of recognition and that failure to correctly diagnose it shows lack of elementary surgical training," is already incontrovertibly refuted in these few passing observations. For, as has just been detailed, many other affections may so resemble or mask the true condition, as to hopelessly perplex the diagnostician and the operator.

Although acute appendicitis may offer difficulties from the clinician's point of view, a clear appreciation of the chief symptoms of the malady should always be indelibly in mind, especially as regards their ordinary arrangement; for, as the late Dr. John B. Murphy remarked: "The order of symptoms is present in 98 per cent. of all cases of acute infection of the appendix. The order of the symptoms is all important in making a diagnosis. If my information were most trustworthy and I were told

that the patient suffered from nausea and vomiting, and that appendicular pain was a later symptom, I would keep in mind the *possibility* of an attack of appendicitis, although its occurrence out of the orderly arrangement of the symptoms would impress me as peculiar."

In order to have at hand a convenient chart of this orderly tabulation of the symptoms, we append the following: Pain, acute and severe, at first referred to the epigastrium, later to the appendicular region, nausea and vomiting, the vomiting occurring twice or thrice, perhaps only once, or there may be no vomiting, only nausea being evidenced; sensitiveness to pressure; elevation of temperature, always present in the acute variety, varies from 99.5° to 104° or 105° due to toxic absorption and leucocytosis.

218 SOUTH FIFTEENTH STREET.

X-RAY TREATMENT OF ACNE VULGARIS.

By W. D. WITHERBEE, M.D.,

AND

JOHN REMER, M.D.,

NEW YORK.

By far the greater number of cases of acne vulgaris, before being referred for x-ray treatment, have been dieted, given tonics had local applications, and received various injections of vaccines. Local applications of sulphur, resorcin, bichloride, beta naphthol, lotio alba, irritant or astringent drugs, cause exfoliation, diminish excessive fat secretion, and thereby overcome the formation of comedones and the accompanying suppurative process.

Although the dose of x-ray necessary to produce effective results, if given properly, produces no ill effects, provided the treatment is not undertaken too soon after the use of any of the above drugs, at the same time it must be borne in mind that the application of any of these drugs during x-ray treatment is absolutely contraindicated in acne as well as in any condition in which x-ray therapy is indicated.

The reason for this is obvious because in order to produce uniform and permanent results it is necessary that the amount of x-ray used should be sufficient to diminish the size of the sebaceous follicles without affecting the skin and its appendages, whereas the combined effect of irritating drugs and x-ray will produce a radio-dermatitis with resultant atrophy, wrinkling of the skin and later telangiectasia. This permanent deformity may not take its appearance until six or eight months after treatment.

Technique.—In order to maintain the same position throughout the exposure the patient is placed in a prone position with a piece of lead foil, cut in the shape of a pair of spectacles, placed over the eyes and held in position by adhesive plaster, thereby protecting the eyes, eyebrows, and eyelashes. Another piece of lead is placed so as to protect the hair over the temporofrontal region. The head is then turned sidewise, having the chin as near as possible in line with the shoulders. The tube is centered over the zygoma and an exposure is given of $\frac{1}{4}$ of 1 skin unit or 1 H. of unfiltered x-ray. The same dose is given to the opposite side. If there are numerous active lesions on the forehead, center of

face, and chin, an additional $\frac{1}{8}$ of a skin unit is given to this area. This is done by having the patient face the tube and measuring the distance from the tip of the nose to the target of the tube. This additional dose to the center of the face should be given only every other treatment.

The routine dose is $\frac{1}{4}$ of a skin unit weekly to each side of the face. This should be continued for two or three weeks after new lesions have ceased to form. Usually this requires from 12 to 16 treatments. In nearly all cases it is wise to give the regular course (12 to 16 treatments) even though the lesions have disappeared after the eighth or tenth treatment. If the chest and back are involved, the dose is the same as that for the face. Three areas are exposed on the back, centering the tube on the outer edge of each scapula and on the 2d lumbar vertebra. The chest is divided into two areas, centering the tube midway between the midaxillary line and the sternum in the 4th intercostal space. Overlapping of areas exposed may be avoided by protection with lead foil.

Recurrences seldom, if ever, take place, provided dietary régime and rational constitutional measures are maintained after a full course of x-ray treatment.

THE NEW BROAD STREET HOSPITAL TECHNIQUE IN ROENTGENOGRAPHY.

A PRELIMINARY COMMUNICATION.

By WILLIAM H. DIEFFENBACH, M.D.,

A. J. BARKER SAVAGE, M.D.,

AND LOUIS FOX, M.D.

NEW YORK.

SINCE the discovery of the x-ray in 1895, there have been several epochs in the development of roentgenography following the discovery of this science.

The evolution of the Coolidge tube, which standardized exposures, a more recent combination of the duplitzed films and the double intensifying screens, presented another step in the gradual perfection of technique.

The construction of the "Bucky diaphragm," which, as is well known, eliminates the secondary rays which so frequently spoil the detail of a plate or film offered another chance for a further development of this science.

The technique in the use of the Bucky diaphragm not having been fully developed, the laboratory of the Broad Street Hospital experimented on a large scale to determine how to secure the best results with the combination of the Coolidge tube, duplitzed films, double intensifying screens, and the Bucky diaphragm.

The result of the experimentation will be shown in the illustrations to be attached to a more detailed article to be published shortly.

We believe that the technique, as we have developed it, is somewhat revolutionary. The attempts of most roentgenologists have been to use a fairly high amperage through the tube with the shortest possible exposure. We, having started to test out the Bucky diaphragm, determined to use a low milliamperage with some longer exposure, and were very much surprised to secure results which

we have never achieved before, and which, to our knowledge, have not been achieved by any other laboratory.

The detail, particularly in bone work, is so superior to the ordinary flat detail secured from the ordinary tube and technique, that a study of the films or of good electrotypes will convince the profession that a step forward has again been made in the remarkable development of x-ray technique.

Briefly, the technique, as we use it at present, consists of placing the Coolidge tube 28 to 30 inches from the upper surface of the Bucky diaphragm, using 8 milliamperage of current, $3\frac{1}{2}$ inches spark gap, and 110 volt circuit, with the following length of exposures: Hand and wrist, up to and including elbow, 2 seconds; knees and shoulders, 4; pelvis, 10 to 15; vertebrae, 10 to 15; skull 8 to 10; sinuses, 10 to 12; gall-bladder, 6; urinary tract, 10; gastrointestinal tract, 1.

We start the Bucky diaphragm a few seconds previous to the exposure and permit it to run several seconds after the exposure is over. We do not use the Bucky diaphragm in all of the cases mentioned, as we believe it to be unnecessary in gastrointestinal work and in soft tissue work. In bone work the remarkable detail and plastic effect is so superior to the ordinary methods that we desire to go on record as strongly recommending our technique in all conditions affecting the osseous system.

We should be pleased if those utilizing this technique and quoting the same would designate it as the "Broad Street Hospital Technique," for it was the resources of this Hospital which permitted the development and application of this new method of roentgenography.

Medicolegal Notes.

Concealment of Material Facts by Insured—Testimony of Medical Examiner.—In an action on a life insurance policy it was sought to defeat recovery on the ground of concealment of material facts by the insured, knowing them to be material, namely, that the insured was not in sound health when the application was made, that the insured, two years before the policy was issued, was afflicted with tuberculous trouble, and under medical advice went to and was treated at the tuberculosis hospital at Kearney. The applicant was examined by a doctor, who testified to the result and that he pronounced her a "first-class risk." The fact that the insured was an inmate of the State tuberculosis hospital for a period of 10 or 12 months was not controverted, but there was testimony in support of the plaintiff's theory that a recovery was had. The doctor's diagnosis was held to support the plaintiff's theory in respect of recovery as disclosed by his own evidence, unless he was mistaken about having made an examination, as he testified, with respect to chest expansion and chest normality, vascular lung murmur, and the like. He also testified that an examination as to pulse force and volume did not seem to be necessary. Assuming, then, that the examination was made, it was clear that his conclusion on these points was the result of his own examination, based upon professional knowledge, and not on the answers of the insured. And if after so extended a personal examination he pronounced her a "first-class risk," and if, as he further testified, there was nothing in her appearance to indicate that she was tuberculous, but was to all appearance in good health, it was held the jury was justified in relying upon his testimony. The question of concealment was one for the jury, who found for the plaintiff.—Fox v. Scandinavian Neut. Aid Assn., Nebraska Supreme Court, 178 N. W. 614.

MEDICAL RECORD.

New York, March 19, 1921.

THE LOCAL FORMATION OF ANTIBODIES.

QUITE recently Topley has undertaken some careful experimental work in order to ascertain whether any evidence could be obtained of the local formation of antibodies or of possible intermediary substances at the site of inoculation of a relatively large dose of a dead bacterial suspension. The method employed was the preparation of an extract of the connective tissue, mainly muscle, into which the suspension had been previously injected and the examination of this in respect to its power of inducing phagocytosis of the homologous bacteria, and its influence, if any, on the phagocytosis of the same bacteria in the presence of normal and of immune serum. A similar tissue extract from a part distant from the site of inoculation was examined as a control. Rabbits were used.

The bacterial suspension was prepared from a strain of the *Staphylococcus aureus*, and the same strain was used throughout, both for the inoculation and for the phagocytic experiments. The injections were invariably made into the thigh muscles of the left leg, the doses usually being 1,000,000,000 dead cocci per kilo body weight of the animal. In a few cases ten times this amount were given. In some experiments a second inoculation was made after a varying number of days, at the same site as the first. In every case a control inoculation consisting of the same volume of saline solution was made into the thigh muscles of the right leg. The extracts were prepared as follows: The animal being anesthetized, the subclavian artery was divided, a sample of blood taken and the animal then allowed to bleed to death. The abdomen was opened and a cannula inserted into the descending aorta and the animal perfused with one liter of sterile saline. When this was completed a portion of the tissues from each thigh, in the immediate vicinity of the inoculation, was removed aseptically. The tissues were finely minced at a temperature of 0° C, and next ground with sterile sand at the same temperature. The mass was then placed in sterile glass tubes and submitted to high speed centrifugalization. The rabbits were killed and the extracts prepared anywhere from one and one-half hours to nine days after. The bacterial suspension used in the phagocytic experiments was always prepared from a twenty-four hours' agar growth of the same organ-

ism employed for inoculation. Washed human leucocytes were invariably used and incubation was carried out in capillary tubes for fifteen minutes at 37° C. In every experiment the extract from the site of inoculation and the control extract were tested for the presence of opsonin and they were likewise tested in the presence of one or more specimens of serum from the animal from which they had been prepared, and occasionally against the serum of a normal rabbit.

There are certain well-known sources of error in experiments of this kind. Such tissue extracts, in a large majority of cases, have the power of binding complement, while their chemical and physical constitution is so complex that the nature and extent of their reactions with serum, quite apart from any antibodies which they might contain, is at present generally known. All the extracts studied by Topley had the power of binding complement, while the routine control test with an extract prepared from a similar tissue remote from the site of inoculation, as well as several control experiments carried out with similar extracts prepared from normal rabbits, showed no evidence of any influence on the degree of phagocytosis induced by normal or immune serum. Titration of the extracts as regards their anticomplementary power showed, in almost every case, that this was abolished by diluting them ten times with normal saline, and in many experiments observations were made on the effect of extracts, diluted to this and to higher degrees, on phagocytosis.

The entire series of experiments gave uniformly negative results. The extracts themselves never induced more than a minimal degree of phagocytosis, neither did they increase or decrease the degree of phagocytosis occurring in the presence of normal or immune serum. The extracts from the tissues at the site of inoculation of the bacterial suspension differed in no demonstrable way from those prepared from other sites in the same animals, nor from similar extracts prepared from normal animals.

Although these results are of only negative interest they form yet another instance of failure to obtain evidence of the local formation of antibodies and from this viewpoint may perhaps render us still more critical of the somewhat slender evidence on which the view that such local production does occur is based. With the exception of von Dungern's experiment, and possibly that of Römer, there is, then, no striking evidence of the production of antibodies by the tissues at the site of inoculation and uncorroborated results can hardly stand against the far greater weight of negative evidence put forward by Topley, Hektoen, and other observers.

GROUP-MEDICINE AND THE YOUNG PRACTITIONER.

MUCH has been said, and much remains to be said, about the advantages and disadvantages of group practice. No phase of the subject is of greater importance than its relation to the young practitioner. This interesting person today finds himself in an

odd position, not to say predicament. Having finished his internship, he has amassed a large bouquet of medical "flowers"; he can agree with Brown-ing's youth, that it were better to

"Strive through acts uncouth

Toward making, than repose on aught found made."

He begins to realize how relatively sheltered his life in school and hospital has been. He begins to realize that the scientific, i.e. the "reputable" institutions are not turning out what a large proportion of our mentally tardy laity seem to want. He sees enormous practices built around bluff and political sagacity. He finds some of his greatest heroes quite unknown to the wallowing public. He sees chiro-practor, osteopath, Christian Scientist, flourishing like the green bay tree. He feels that his is a voice crying in the wilderness—only it is not ethical for him to cry very loudly. Legislators, being only laymen who do their wallowing in capitol, are not likely to give ear to the voice of his complaints against quackery.

No, the "legitimate profession" seems to have decided upon a campaign of overcoming evil with good. Incidentally, it is probably the only effective way. The grade A schools are turning out men trained to function so well that their only hope is in the public waking up and beginning to discriminate—so that the quacks will undergo starvation necrosis.

There are three alternatives for the young medical graduate. He can fare forth "on his own"; he can work as an older man's assistant; or he can join a group. He who works alone may get various "jobs," remunerative or otherwise (more often otherwise), of educational value or not, while he is waiting for patients. He must accustom himself, and perhaps his wife, to the process of starving along. Many a young practitioner is coming to realize that the shortest way to self-support leads through the smaller towns and suburbs. There, though he may not rise to the dizzy heights, he will at least "arrive" more quickly. The alternative of becoming somebody's assistant allays many of those financial pangs to which young medical men are subject. If he can work along assiduously for a time, content to shine by reflected light, and eventually "fall into the old man's practice," many a bramble and boulder will be taken out of his path.

It is natural, however, that when a young man with thorough hospital training is invited to join a group, he should accept with alacrity. It offers him an opportunity to do the work for which he is best fitted, and patients and a relatively reliable financial intake are to a considerable extent assured—more so, at any rate, than if he were a separate entity.

Granting the ability of the group to get along amicably together, to arrange finances satisfactorily, to behave generously toward other groups or individuals, to refrain from charging exorbitantly, etc., group practice is in a fair way to become an excellent medium through which the public may profit by the recent advances of modern medicine, and the recent hospital graduate occupy a position of financial solvency at no cost to his self respect.

SENSITIVENESS TO BLINDING RAYS.

THE German expression *Blendungsschmerz* has no familiar equivalent in English. In its native speech it is of vague connotation, apparently applying to any painful sensation which accompanies photophobia. It is necessary that very strong light rays impinge on the retina more or less suddenly and produce transitory inability to see, accompanied by sensations of pain. There is a spastic closure of the orbicularis muscle which may stand in some definite relation with the painful sensations. The subject of *Blendungsschmerz* is considered exhaustively in an article by Siegwart in the *Schweizerischer medizinische Wochenschrift* for December 16, 1920, i, 51. Numerous experiments have been made to determine the nature of these sensations. Thus in 1901 Nagel after adapting the eyes of a normal subject to the dark chamber exposed them suddenly to strong sunlight. The subject complained of blinding pain, whereupon the experiment was repeated with atropinized eyes and the blinding pain was no longer perceived. Nagel therefore referred the pain to the iris. These experiments were repeated by Roemer with six subjects, not one of whom felt pain on the transition from darkness to strong light. Nagel sustained his own claims, and Axenfeld, who made experiments, was obliged to endorse them. Nicolai and Feilchenfeld then repeated the experiments on an extensive scale with many variations. The conclusions were that there is a phenomenon in which pain is associated with sudden contraction of the pupils in exposure to the light, this being physiological; but that there may be a pathological component in which the retina is involved along with the iris. Further study showed that mild pathological conditions may be at fault in blinding pain. Thus there are retinal hyperesthesia of neurasthenics, certain cases of nyctalopia, chronic nictinism, total color blindness, and irritable conditions of the trigeminus and optic nerves which can motivate blinding pain in seeing eyes.

Several curious facts have recently been brought out in connection with the blinding pain, but with the author we may now pass to the special field of the blind eyes. He recognizes four possible sources of pain, viz., spasm of the orbicularis, contraction of the pupil, irritability of the retina, and irritability of the trigeminus nerves. A distinction must first be made between the totally blind and the one-eyed, for in the latter the pain may be felt in the sound eye. The light used was either the noon sun or on dark days a 150 candle power lamp. The number of subjects tested was about 50, blind, nearly blind, and one-eyed. In not one case was blinding pain felt save in certain inflammations where there was a consensual pupillary reflex, the light being applied to the seeing eye. Generally speaking there is no pain if the perception of light is lost. If the retina be insensitive there is no pupillary reflex to light. The length of the light rays is not a component as shown by testing the various sections of the spectrum.

MAGENDIE'S ANTICIPATION OF THE DISCOVERY OF VITAMINES.

ACCORDING to Professor Sabrazès, writing editorially in the *Gazette hebdomadaire des sciences médicales de Bordeaux*, November 24, 1920, xli, 41, Magendie anticipated the discovery of vitamins by nearly a century. This illustrious man, whose position in the history of biological science is somewhat underrated, was the teacher and predecessor of Claude Bernard, whose eminence served to obscure the merits of the older man. Magendie found a world in which experiment had virtually been abandoned, and was compelled to blaze a new trail. It was said of him by enemies that he made "many experiments and few discoveries," but he was a sceptic and followed the advice of Descartes to doubt everything until it could be proven. He doubted all that had been taught in speculative fashion, all theories and systems. This extended to therapeutics, and so great was his nihilism that he was looked on as having no constructive ambition at all. Nevertheless he was largely responsible for the introduction of such valuable drug principles as morphine, strychnine, iodine, ipecac, etc., while in other branches of medicine he was equally a pioneer. The reference to something akin to vitamins is taken from the third edition of his textbook on physiology (1833), in the chapter on nutrition. Here he makes the statement that something more than nitrogen is necessary to sustain life, and if sugar and oil constitute the sole diet the cornea ulcerates. There is a capital difference between the white bread made from fine wheat flour and the so-called military bread made of the whole grains. The latter one could subsist on wholly, the former lacked something necessary for life. Animals fed on one kind of grain like polished rice (*viz glacé*) perished. There was a curative substance in muscle (osmazome) which could offset the state of denutrition due to living solely on white bread. Further extracts seems unnecessary, for Magendie had the essentials of the vitamin theory.

SECONDARY TUMORS OF THE BONES.

IN an address before the Academy of Medicine of Paris, on this subject, a report of which appears in *Le Bulletin Médical* for November 20, 1920, xxxiv, 55, Delbet refers to those secondary tumors which impose themselves as primary. On a previous occasion he showed that a tumor of the clavicle was a metastasis of a cancer of the stomach. The subject is less simple than it appears, for a histological diagnosis may lead to error. In some of these metastases it is difficult to find any epithelial tissue. The author once made a diagnosis of primary sarcoma of a bone—the olecranon, but it was found later to have been a cancerous metastasis from a cancer of the breast. In the secondary cancer the microscope may show myeloplaxes which do not occur in epithelioma, but are very common in primary sarcoma of bone. Study of the literature shows that so-called primary sarcoma must often have been secondary cancer. Especially when they develop in the epiphyses, there is no clinical method for differentiation. In the diaphyses it may be otherwise, for in this location sarcoma is not common while secondary epithelioma is almost always

diaphyseal. In regard to the spontaneous fracture which betrays the presence of a malignant growth, one cannot generalize sharply. The author has seen two cases of cancer which were manifested in this way. In sarcoma of the diaphyses there should be pain, disability, and tumor before fracture develops. But in some cases, at least, of secondary cancer fracture is the first symptom. When many portions of the skeleton are simultaneously attacked we do not think of multiple primary sarcoma but of multiple osseous metastases of cancer. The author once x-rayed a subject with spontaneous fracture of the humerus and made the diagnosis of osteosarcoma, performing a resection of the bone. Subsequent metastases showed that the condition was cancerous, the primary focus being apparently in the thyroid.

News of the Week.

Immunizing Against Diphtheria.—During the past few months the Department of Health of Detroit has given the Schick test to more than two thousand school children and protective treatment with toxin-antitoxin to about eight hundred. The Board of Health of Detroit furnishes the materials for diphtheria prophylaxis to physicians and gives them any assistance desired in regard to technique. The same work has been under way in New York City for some time under the direction of Dr. Abraham Zingher of the Board of Health. It is stated that some ten thousand children have already been tested and those found susceptible have been immunized.

New Typhus Cases Among Immigrants.—Five new cases of typhus fever were discovered on March 7 among the immigrants who arrived on the Italian liner *San Giusto*, which brought twenty cases of typhus fever to the Port of New York several weeks ago. On the same date a sixth case was taken from the *Kroonland*, which arrived on March 3. These cases were isolated with the other forty cases now being cared for on Swinburne Island.

Dr. G. Canby Robinson has been elected to the position of professor of medicine and dean in the Vanderbilt School of Medicine, Nashville, Tenn. He enters on his active duties there in September, 1921.

A Correction.—In the MEDICAL RECORD of February 12 in the last paragraph of the item on "Misbranding Drugs Alleged to Have No Curative Value," on page 271, it was stated that "the law does not reach one who puts inert matter or a worthless composition in the channels of trade, labeled as a cure for disease when he knows it is not." The first negative in this sentence crept in through error, for, in fact, the court held that the law was applicable in such cases.

Oregon Makes State-Wide Survey of Mental Defects.—This survey, which was authorized by the Oregon Legislature and carried out by the University of Oregon in collaboration with Dr. C. L. Carlisle of the United States Public Health Service, is the first State-wide survey which even begins to disclose the enormous drain on a State caused by mental defects. That more than 75,000 men, women, and children out of a total popula-

tion of 783,000 are dependents, delinquents, or feeble-minded, are unable either to work or fight, and are a constant drain on the finances, health, and morality of the State is the startling result brought out by the survey in Oregon. Out of a total school enrolled population of 32,500, more than 500 were found to be more or less mentally deficient. The figures yielded by the Oregon survey are considerably lower than the average shown by the draft examination, a fact that indicates, in the opinion of the Public Health Service officers, that they are certainly not higher than those that would be obtained by similar surveys in other States. Very few of the types of mental defects revealed by this survey are being cared for in institutions. The rest are widely scattered and were practically unknown until the survey was made. In submitting this report the Public Health Service emphasizes the importance of the problem presented by mental defectiveness in its relation to juvenile delinquency, to the control of venereal disease, and to the economic and industrial condition of these defective individuals.

Smallpox in Constantinople.—A cablegram under date of March 8 states that smallpox has been added to the list of diseases prevalent in that city. A sailor on the United States destroyer *Overton*, cruising in Turkish waters, has died of smallpox. The *Overton* has been isolated in the sea of Marmora.

Doctors May Prescribe Wine and Beer.—An opinion handed down by Attorney General Palmer, on March 3, holds that it is not within the power of the Internal Revenue Bureau, through regulations, to limit the number of permits which may be issued for the manufacture and sale of spirituous, vinous, or malt liquors for medicinal purposes, except that permits for retail sale are limited to reputable druggists who are pharmacists. Mr. Palmer holds further that while the Volstead act fixed at one pint the maximum amount of spirituous liquor which a physician might prescribe for any patient during ten days, no such restriction has been placed upon the use of beer and wine for medicinal purposes. It was held, however, that regulations could be formulated which would prevent a physician from prescribing at one time a large quantity of liquor, which might never be required for the purpose for which it was prescribed.

Massachusetts Lepers Moved South.—The leper colony that Massachusetts has maintained at Penikese Island, in Buzzards Bay, was evacuated on March 10, and the thirteen members started by special car for the Federal leprosarium at Carville, La. On its way the car will pick up three additional unfortunates, one at Bridgeport, Conn., and two at Richmond, Va. Some of these lepers had been members of the Penikese colony since it was established thirteen years ago.

New White House Physician to Study Public Welfare.—Dr. Charles E. Sawyer of Marion, Ohio, has been nominated by President Harding to be the White House physician, and also a brigadier general in the Medical Reserve Corps of the army. In connection with the appointment an official announcement states that "President Harding has long since been convinced that affairs re-

lating to public welfare, such as public health, education, and social justice, are so intimately related, and so vital to the nation's perpetuity, that he has decided to begin at once a careful survey of all matters pertaining to these subjects. Dr. Sawyer will be given authority to make a thorough investigation of the needs along these lines and to present the accumulated facts with such suggestions as his observations may warrant in bringing about a concrete plan of co-ordination and efficient economic organization of these affairs." Dr. Sawyer's duties are to begin immediately.

New York's Narcotic Squad Makes Record.—Dr. Carleton Simon, Special Deputy Police Commissioner, has submitted a report covering his activities for the past four months as head of the narcotic division, which shows that 1,000 arrests have been made for violation of the antinarcotic law and that 95 per cent. of those brought to trial have been convicted. During this period more than \$1,000,000 worth of drugs has been confiscated.

Mr. Arthur Macdonald of Washington, D. C., has been recommended to President Harding by numerous scientific bodies for appointment as Director of Census.

Dr. Smith Ely Jelliffe of New York has been elected to honorary membership in the Société de Médecine Mentale de Belgique at its recent reunion.

Dr. C. L. Alsberg, chief of the Bureau of Chemistry of the United States Department of Agriculture, has been appointed a director of the Food Research Institute which is to be established at Stanford University, California, according to an announcement made by the Carnegie Corporation.

Red Cross Leaders Off to Geneva Conference.—Four national officers of the American Red Cross sailed on the *Imperator* on March 12 to represent the society at the tenth international conference which opens at Geneva on March 30. These officers are: Dr. Livingston Farrand, chairman of the central committee; Dr. Albert Ross Hill, vice-chairman in charge of foreign relations; Eliot Wadsworth of Boston, and George E. Scott of Chicago.

New York University Medical College Alumni Reunion.—The alumni of New York University Medical College will hold their second annual dinner at the Hotel Biltmore, New York City, on Thursday evening, March 31, 1921. The dinner will be the occasion of class reunions. The committee in charge of arrangements for the dinner are Dr. Robert J. Wilson, Dr. Herman A. Haubold, and Dr. John A. Mandel.

Vacancies in St. Elizabeth's Hospital.—The United States Civil Service Commission announces an open competitive examination for the position of medical interne in St. Elizabeth's Hospital, Washington, D. C., and vacancies in positions requiring similar qualifications. The positions pay \$1,200 a year and maintenance. Applicants must be graduates of a reputable medical college, or senior students in such an institution. They must not have graduated previous to the year 1915 unless they have been continuously engaged in hospital, laboratory, or research work along the lines

of psychiatry or neurology since graduation. Those desiring to take the examination should apply at once for Form 1312, stating the title of the examination desired, to the United States Civil Service Commission, Washington, D. C.

New York Association for Medical Education Reorganizes.—At its annual meeting, held at the New York Academy of Medicine, March 7, 1921, this association amended its by-laws and reconstituted its board of directors to apportion the control of its affairs among the five medical schools of Greater New York, namely, Columbia University, College of Physicians and Surgeons; Cornell University Medical College; Long Island Medical College Hospital; New York Post-Graduate Medical School and Hospital, and the University and Bellevue Hospital Medical College. These five medical schools will co-operate to develop New York City as a medical teaching center. Unnecessary duplication of courses of instruction by the several medical schools will be done away with, and a higher type of graduate work will be instituted. The newly elected officers of the association are: President, Dr. Haven Emerson; secretary, Dr. Otto V. Huffman; treasurer, Dr. George W. Kosmak. The new board of directors is as follows: Columbia University, College of Physicians and Surgeons, Dr. William Darrach, Dr. Frederick Tilney, Dr. Charles N. Dowd, Dr. Walter A. Bastedo; Cornell University Medical College, Dr. Henry H. M. Lyle, Dr. John A. Hartwell, Dr. James Ewing, Dr. Walter L. Niles; Long Island College Hospital, Dr. Adam M. Miller, Dr. John Osborn Polak, Dr. Luther Fiske Warren, Dr. Emil Goetsch; New York Post-Graduate Medical School and Hospital, Dr. James F. McKernon, Dr. Arthur F. Chace, Dr. J. Bently Squier, Dr. Ludwig Kast; University and Bellevue Hospital Medical College, Dr. Samuel Brown, Dr. William H. Park, Dr. Charles A. Elsborg, Dr. Hermann M. Biggs; for the profession at large: Dr. William H. Bishop, Dr. William Francis Campbell, Dr. Lewis A. Connor, Dr. Adrian Lambert, Dr. Alexander Lambert, Dr. Emanuel Libman, Dr. James A. Miller, Dr. Eugene Pool, Dr. Thomas F. Reilly, Dr. Bernard Sachs, Dr. Thomas W. Salmon, Dr. George Gray Ward, Jr.

The Leonard Prize for Research.—The American Roentgen Ray Society announces that it will award \$1,000 to the author of the best piece of original research in the field of x-ray, radium, or radioactivity. This prize is offered with the approval of the National Research Council and commemorates the name of a martyred member of the American Roentgen Ray Society, Dr. Charles Lester Leonard. The conditions of competition may be obtained by application to any of the committee: Dr. A. W. Crane, 420 South Rose Street, Kalamazoo, Mich.; Dr. P. M. Hickey, 32 Adams Avenue, W. Detroit, Mich.; Dr. Henry K. Pancoast, University Hospital, Philadelphia, Pa.

The American Congress on Internal Medicine, at its annual meeting held at Baltimore, February 21-26, 1921, elected the following officers for the ensuing year: *President*, Dr. Sydney R. Miller, Baltimore, Md.; *First Vice-President*, Dr. Ellsworth S. Smith, St. Louis, Mo.; *Second Vice-President*, Dr. James Rae Arneill, Denver, Col.; *Secretary-General*,

Dr. Frank Smithies, Chicago, Ill.; *Treasurer*, Dr. Clement R. Jones, Pittsburgh, Pa.

Gifts and Bequests.—Among the bequests made by the will of the late Mrs. Speyer is one of \$5,000 for St. Mary's Free Hospital for Children. A fund of \$20,000 donated by Edward Hatch, Jr., to charitable purposes is distributed as follows: Dr. Louis Fischer's Infantorium for the shelter of infants from birth to one year of age, \$2,500; Columbus Hill Day Nursery, \$2,500; Placing-out Department of Nursing and Child's Hospital, \$2,500; Alice Chapin Adoption Nursery, \$2,500; the Crèche, Englewood, N. J., for the care of convalescent and homeless babies, \$2,500, and St. John's Guild for day boat excursions for sick and ailing babies during the summer months, \$5,000.

Effective War Against Typhus in Poland.—The American Red Cross has just issued a statement stating that five hospital trains of ten cars each are now being used in the battle to prevent the spread of typhus in Poland. The announcement adds that the thoroughness of the Red Cross campaign in Poland is proving exceptionally effective in limiting the spread of the disease.

Biltmore Hospital Burns.—The Biltmore Hospital, near Asheville, N. C., was destroyed by fire on March 5. The patients were all carried to safety.

Heart Beats Studied by Amplifying Apparatus.—An amplifying and transmitting apparatus was demonstrated at the Army Signal Corps Laboratories in Washington, on March 12, which increases the heart sounds many times, and by means of electrical connections transmits them so that they may be studied by a physician in another room or even hundreds of miles away. The principle involved is that employed in transmitting addresses. The device, which rests over the patient's heart, may be used in connection with any telephone wires and will function as far as the telephone wires will transmit the voice in ordinary conversation.

Obituary Notes.—Dr. GEORGE HASTING CLOSE of New York City died suddenly on March 11, at the age of forty-eight years. He was graduated from Bellevue Hospital Medical College in 1899, and was a member of the New York Academy of Medicine.

Dr. ALFRED BENNISON ATHERTON, formerly of Frederickton, N. B., and later of Toronto, died in San Diego, Cal., after a long illness, on March 7, at the age of seventy-eight years. He was a graduate of Harvard Medical School in 1866, and one of the founders of the American College of Surgeons.

REPORT OF THE PUBLIC HEALTH COMMITTEE ON TYPHUS.

THE Public Health Committee of the New York Academy of Medicine has made the following statement with regard to the typhus fever situation:

The occurrence of typhus fever in New York City is not an extraordinary event. At no time has the city been entirely free from typhus fever. It has lingered here endemically for years, appearing in the mild form called "Brill's disease." The summaries of reportable diseases in the weekly bulletin of the Health Department do not include statistics of typhus, but in the annual reports mention is made of its existence. In 1917 twenty-four cases were reported, and in 1918 thirteen cases. In connection with these cases the Health De-

partment report states that "none of those affected were recent immigrants nor had they been in contact with those who had recently arrived in this country." Among the cases also which have recently occurred, some are reported to be of local origin and not in any way connected with the cases originating on the other side.

In considering the measures for the prevention of typhus fever one should bear in mind the essential facts connected with the transmission of the disease:

(1) It is an established fact that the infective agent of typhus fever is contained in the blood of the typhus sick; (2) it is an established fact that the virus of the disease is found in the stomach and intestinal tract of lice which have fed on blood of the typhus sick; and (3) it is an established fact that a louse which has fed on the blood of an infected individual can transmit the disease to a well person through the virus contained in its excreta.

The segregation, therefore, of the sick from the healthy, and the destruction of the carrier which is known to be the louse, particularly the *Pediculus corporis*, are absolutely essential to prevent the dissemination of the disease. As typhus fever during epidemics may affect individuals in such a mild form as to escape the detection even of trained physicians, and as infected lice may be carried from districts where epidemic typhus exists and may thrive on the bodies and in the clothing of those who are naturally immune or who have become so after an attack of the disease, no other method than the destruction of all lice living on the persons and in the clothing or bedding of those who come from typhus-infected districts, will prevent the transmission of the disease. In the past this had not been recognized by quarantine authorities, who have considered it necessary to delouse only such vermin-infested individuals as arrive on ships on which typhus existed or had recently existed. It would seem essential, therefore, that disinfestation should be applied to all immigrants coming from countries where the disease is prevalent, whether arriving on typhus ships or on ships free from typhus.

It is imperative furthermore that this process should be applied at the port of embarkation, to prevent as far as possible the infestation of persons and ships. As an additional precaution, wherever feasible, it would be most desirable to reexamine during the course of the voyage all those immigrants who before embarkation went through the delousing process, and immediately to subject such as were still infested together with their clothing and effects, to a delousing process while still on board. On arrival here, those individuals on whom lice were again found, together with their clothing, bedding, and effects, should be once more subjected to cleansing and delousing.

The necessity of preembarkation measures has been recognized by the United States Public Health Service. No vessels sailing from foreign ports receive bills of health from American consuls until the passengers have been satisfactorily disinfested. That this requirement should be strictly enforced is distinctly to the advantage of the steamship companies, as an outbreak of illness among the passengers results in clearing delays and involves extra expense at American ports of disembarkation.

The sanitary authorities have always been on guard against the introduction of typhus from abroad, and particular watchfulness has been exercised since our troops began to return from Europe. The effects of the sanitary cordon established have been salutary, as the methods of control are well known, and by their diligent application typhus fever can be well held in check.

No imminent danger of the spread of typhus fever exists. Nevertheless no effort should be abated on the part of the Federal and local health authorities, each in their respective fields, to minimize the possibility of the introduction and spread of the disease.

Should the existing facilities at quarantine prove inadequate for the task, the Public Health Committee of the New York Academy of Medicine would recommend immediate equipment of additional facilities, with the possible cooperation of the navy and army sanitary departments, for ridding incoming persons and their effects of vermin in an adequate and efficient manner.

Because of the existence of the endemic type of typhus fever in this city, if for no other reason, the efforts of the City Health Department should be directed toward the elimination of pediculosis, from which a considerable portion of the city population suffers. The reports of school inspections show that every year over 200,000 children are found to be infested with lice. The weekly bulletin of the Department of Health of this city of April 5, 1919, states that it is regarded as remarkable when the graduating class at the end of the last term of public school in this city had not over 10 per cent. of its members infested with lice. This reflects the home conditions obtaining in certain sections of the city. It would seem, therefore, that no effort should be spared to rid our own population of the extensive prevalence of pediculosis.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, February 22, 1921.

The Milk Amendment Bill.—It is generally allowed that the milk regulations in force in this country are inadequate to insure a supply of pure milk sufficient for the proper nutrition of the infant and child population. A considerable proportion of the infants of Great Britain are not breast fed but rely for their sustenance upon cow's milk and artificial feeding of one kind or another. This being so, it seems essential in the interests of the nation, especially when as now the value of child life is so strikingly obvious, that steps should be taken to safeguard the milk as far as is possible. But up to the present time the steps taken with this end in view have been wholly inadequate. Moreover, during the last fifty years the production of milk in Great Britain has failed entirely to keep pace with the growth of population. Recently the Minister of Health has introduced a bill to secure amendments to the machinery provided by the Milk and Dairies Act of 1915. An important Milk and Dairies Act was passed in August, 1914, the operation of which was postponed to a date within one year after the war. The Act of 1915 provided no new legislation, but consolidated in one act that of 1914 and those provisions in previous acts which still remained operative. The main provisions of the Milk Amendment Bill, which now awaits its second reading, are as follows: (1) Provision for the licensing of dairymen and dairies. (2) Provision for the undertaking by sanitary authorities, with the approval of the Minister of Health, of the supply and distribution of milk, or the cleansing, storage, etc., of milk for sale by dealers. (3) An extension of the provisions of the 1913 Act in regard to the classification of milk. (4) The constitution of Milk and Dairies Committees by the local authorities who will administer the act. In the final Report of the Committee on the Production and Distribution of Milk issued some little time ago, it was stated that in the opinion of the committee the milk supply, in addition to being quite inadequate, was as a whole in a most unsatisfactory condition from the point of view of pollution and infection. The care of the milk supply in America and Great Britain was compared, greatly to the disadvantage of that of the latter country. The committee also drew attention to

the great value of properly dried milk. The following are the most important items of what is termed by the committee an enlightened milk policy: (1) To bring about the utmost possible economy in production in order that (a) consumption of milk may be increased to the desired level; (b) an adequate supply of milk may be brought within the reach of the poorest families; (2) To improve the hygienic quality of milk. (3) To increase the total supply in order to meet the extended consumption that should follow improved quality and the education of the public with regard to the nutritive properties of milk. It is now required by the amended bill that all dairies and dairymen shall be licensed. Many of those best competent to judge hold that the bill does not go nearly far enough and that the milk supply in the large British cities will remain unsatisfactory until all milk is bottled in sterilized bottles or other necessary measures are taken to safeguard it.

Determination of Sex.—Dr. W. Bateson delivered a lecture the other day on the heredity of sex. He said in part that the point he mainly wished his audience to carry away very clearly in their minds is that sex determination is a problem that can be investigated and that accurate knowledge can be and has been brought to bear on it. In all probability these determinations are made in the development of the germ cells and that having been made in essentials they are fixed. The speaker went on to say that in old days it was accepted as a fact that we could not see any deeper into the mystery of sex, and that we could not show how it came about that there were two sexes. Only five years ago it was thought that practically there was no way of predetermining sex; but facts were now being ascertained which showed that sex could be determined in certain moths and frogs by a process of hybridization. It had now been established that by means of cross-breeding in moths, we could alter the proportion of sexes by interference in the fertilization. As for color blindness Dr. Bateson said that if a man who is color-blind marries a woman who is normal their children will probably be without the defect, which will reappear in the next generation when the daughters marry. The blindness is perpetuated through the daughters and not through the sons and is far more common among women than men. It is estimated that 5 per cent. of the population are color blind.

Dr. Annie Louise McLroy.—Dr. A. L. McLroy has been appointed to the Chair of Obstetrics and Gynecology at the London School of Medicine for Women. She will also be in charge of the newly established unit in Gynecology and Obstetrics at the Royal Free Hospital, Grey's Inn Road, London. Since her student days at Glasgow she has had a varied experience in gynecological work, mainly at the Glasgow Royal Infirmary, where before the war she was senior assistant to the Muirhead Professor of Obstetrics and Gynecology and Senior Assistant Gynecological Surgeon. During the war Dr. McLroy served abroad as surgeon-in-charge of the Scottish Women's Hospital at Salonica and Belgrade. Later she acted as gynecological specialist (R. A. M. C.) at the Eighty-second General Hospital at Constantinople. The appointment affords striking evidence of the progress made by women recently in medicine and surgery. Not many years ago such an appointment would have been impossible. The position carries a salary of £2,000 a year.

The Chair of Embryology at University College, London.—The Chair of Embryology, instituted at University College, London, as one result of the Rockefeller gift, has just been filled by the appointment of Professor J. P. Hill, who gained his experience as lecturer on embryology in the University of Sydney. Since 1906 he has been Jodrell Professor of Zoology and Comparative Anatomy at University College.

International Organization and Public Health.—As mentioned in a previous letter the International Health Organization was formed as the result of a series of resolutions passed by the Assembly of the League of Nations at Geneva in December last. Dr. G. S. Buchanan, C.B., gave an address on the subject before the British Society of Medical Officers of Health on February 18, 1921. Dr. Buchanan was nominated by the Ministry of Health to be the technical adviser on this subject to the British delegation. It may be remembered that by the Covenant of the League of Nations, which forms an integral part of that treaty, the members of the League undertake to initiate measures in matters of international concern for the prevention and control of disease. The League is also empowered to take over the direction of international bureaus established by general treaties, among which is included the existing Office International d'Hygiene Publique, which was established by the Convention of Rome, 1907. The objects of the International Organization are stated as follows in the resolutions of the Assembly. As Dr. Buchanan pointed out, it will be seen that their terms are safely guarded: (1) To advise the League of Nations in matters affecting health. (2) To bring administrative health authorities in different countries into closer relationship with each other. (3) To organize means of more rapid interchange of information on matters where immediate precautions against disease may be required (*e.g.* epidemics) and to simplify methods for acting rapidly on such information where it affects more than one country. (4) To furnish a ready organization for securing or revising necessary international agreements for administrative action in matters of health and more particularly for examining those subjects which it is proposed to bring before the standing and general committees, with a view to international conventions. (5) In regard to measures for the protection of the worker against sickness, disease, and injury arising out of his employment, which fall within the province of the International Labor Organization, the International Health Organization will cooperate with and assist the International Labor Organization, it being understood that the International Labor Organization will on its side act in consultation with the International Health Organization in regard to all health matters. (6) To confer and cooperate with International Red

Cross societies and other similar societies under Article 25 of the Covenant. (7) To advise, when requested, other voluntary organizations on health matters of international concern. (8) To organize missions in connection with matters of health at the request of the League of Nations, and with the concurrence of the countries affected within the limits proposed by sub-paragraph (a) or by the International Convention of Rome (1907). Dr. Buchanan pointed out that the League of Nations will have its budget control, a certain power of withholding sanction to action proposed by the organizations, the right of sanctioning appointments of paid officers and of receiving reports, but, apart from these, the general working of the organization, the regulation of its internal affairs, and the appointment of staff is left entirely to the organization itself, in other words, to the public health men themselves. Dr. Buchanan emphasizes the fact that here is the opportunity of the public health officers and hopes that they will not only be willing to seize it (this may be taken for granted), but will find themselves in position to give necessary time and labor to insure its success and be supported in their respective countries by departments which realize that practical international action and agreement is a fundamental part of any good State public health policy.

State Insurance Funds.—The first valuation of the assets and liabilities of approved societies under the National Health Insurance Act show a surplus of £3,600,000 (\$18,000,000) or over £1 6s. (\$6.50) per insured person. That means, in effect, that the societies have a substantial sum to distribute to their members, which may take the form of increased monetary grants during illness or may be devoted to the maintenance and treatment of members in hospitals and convalescent homes, dental treatment, optical treatment, the provision of nurses in the home, and other essential medical services. Most of the larger societies are still in process of valuation, and it is anticipated that the total surplus will be between £8,000,000 and £9,000,000. The above mentioned benefits are some of the additional benefits which societies may choose as most suitable for the needs of the members. They are set out in the acts and regulations governing National Health Insurance. They cover no fewer than eighteen different forms of benefit, and the members of each society in general meetings have the right to select the type or types of additional benefits they prefer, subject to their inclusion in a scheme which is to be submitted to and approved by the Minister of Health on the corresponding authority in Scotland or Ireland. In view of the present high cost of living, it is possible that some societies will decide to devote part of their surpluses to increasing the cash benefits under the Act, but the Minister has taken the opportunity, when sending out the valuer's report, of reminding its executive that the prevention and cure of sickness is one of the main objects of the National Health Insurance Act, and of impressing upon them the desirability of adopting schemes which will improve the standard of health among their members and incidentally lessen the drain upon their sickness funds. Quite recently a regulation has been made

allowing the surplus in societies to be devoted in whole or in part to the maintenance and treatment of members in hospitals and convalescent homes, and it is anticipated, especially in view of the present financial necessities of the hospitals, that a considerable number of societies will make arrangement for the institutional treatment of their members. Although some of the largest societies, as mentioned previously, have not yet received their valuation reports, and consequently are not yet in a position to arrange a scheme of additional benefits, the Minister of Health is aware that they are contemplating making arrangements with hospitals for the treatment of their members in preference to an increase in cash benefits. Dental treatment is another additional treatment under the Act, and in view of the volume of sickness among members of approved societies which is directly attributable to dental decay, it is anticipated that quite a number of schemes of free dental treatment will be put forward by societies. Other forms of additional benefits include the service of nurses for members and medical treatment and medical attendance for the families and dependents of members.

Berlin Professor Made an Honorary Member of the British Society for the Study of Sex Psychology.—Dr. Iwan Bloch, a Berlin authority on sexual pathology and psychology, has been elected to an honorary membership of the British Society for the Study of Sex Psychology, thus forging the first link in the long sundered chain of scientific relations between England and Germany. Like many other German men of science, a Fellow of the Royal Society of Medicine before the war, Dr. Bloch is, as far as can be ascertained, the first doctor of medicine to whom the hand of friendship has been extended since peace was signed.

Visit to London of French Physician.—An official representative of the Faculty of Medicine of Paris, Dr. Monod is about to be sent to London to promote the medical entente existing between the two nations. During the course of his visit he has arranged to give a demonstration before the Fellowship of Medicine at the House of the Royal Society of Medicine, on February 23, of a new French appliance, the ultra cinema. It is stated that by means of this appliance, the movements of the heart can be observed, athletic movements and so on. However, four distinct objects are concerned in Dr. Monod's visit: (1) To offer the Fellowship of Medicine representation in the Faculty of Medicine, Paris. (2) To endeavor to arrange exchanges of professors between the two countries. (3) To insure proper exchanges of literature and of reviews by competent critics. (4) To lay the foundation of a strong Anglo-French Medical Association.

Obituary.—One of the best-known medical men in Dublin, indeed in Ireland, Dr. J. C. MacWalter, died very suddenly on the morning of February 12. Dr. MacWalter was born in America and came when young to Dublin, where he qualified as a pharmaceutical chemist. He then took up the study of medicine and in 1897 obtained the diplomas of the Royal College of Surgeons in Ireland and of the Apothecaries' Hall. However,

he was not content to rest here and in 1900 he became a Fellow of the Faculty of Physicians and Surgeons of Glasgow, and received the diploma of Public Health of the Royal Colleges of Ireland. In subsequent years he took the Degrees in Arts and Law of the National University of Ireland, the Doctorates of Medicine of Brussels and Durham, and Degrees in Arts and Medicine of Dublin University. He was called to the Irish Bar in 1907. While reading for these various degrees he was at the same time hard at work at medical practice, as well as supervising a large pharmacy with many branches. Dr. MacWalter took an active part in the public life of Dublin. He was for many years an alderman of the city and for the past year he was high sheriff. He was a member of many medical societies and a facile, interesting, and energetic writer. He was a frequent contributor to the pages of the *Medical Press and Circular*. In 1915 he applied for and received a commission in the Royal Army Medical Corps, serving in Malta, Egypt, and Salonica, and then for a time with the Air Force in England.

Dr. David Yellowless, formerly physician-superintendent of the Royal Asylum, Gartnavel, Scotland, died in Edinburgh on January 19. During the twenty-seven years that he was at the head of the Royal Asylum he was recognized as a leading authority on mental diseases. Dr. Yellowless was Lecturer on Insanity in Glasgow University. He was President of the Psychological Section of the British Medical Association, held in Glasgow in 1888, and the same year the degree of LL.D. was conferred upon him by the University of Glasgow. He was an honorary member of several foreign scientific societies. Dr. Yellowless was a very good teacher and a man of the highest integrity.

LETTER FROM GENEVA.

(From Our Own Correspondent.)

GENEVA, Feb. 25, 1921.

Life and Works of Galen.—The regular monthly lecture before the Medical Society of Geneva in January was delivered by Dr. Cumston, his subject being: "Galen: His Character and Works." The lecturer referred to the second century of our era as being one of the most glorious epochs of the conquest of Rome by the Greeks and thus the most illustrious name of all the learned of the time was that of Galen. That most of Galen's principles were excellent there was no doubt; they sum up the entire field of therapeutics which even at the present time, is based upon them. Unfortunately, Galen was not content to expose his doctrines clearly and briefly. Too fond of complicated systems and explanations, he often neglected the practical side of the new ideas emitted, and his successors—too faithful to his doctrines and still more heedless than their master—became buried in the mud of vain theories. For centuries to follow the Galen who disserts will be to physicians what Aristotle was to philosophers, and Galen's bristling and rich logic hid those practical precepts which otherwise would have hastened the progress of the medical sciences in their development. The two great names—Galen and Aristotle—were much the same in

history. During the medieval times Aristotle's authority destroyed that of Pythagoras, Epicure, and Plato; Galen's authority almost completely destroyed the remembrance of Hippocrates. Those who were to reign over the schools and give such impetus to scholasticism were the two Peripatetics—the philosopher who discovered the doctrine of the elements, the four qualities and the four humors, and the physician who, applying these to the cure of disease subjected the human organism to them. The glory of each walked hand in hand.

The Revilliod-Julliard Lectures.—Dr. Francis G. Crookshank, F.R.C.P., of London, will be the Revilliod-Julliard lecturer before the Medical Society of Geneva for this year. The title of the lectures is, "The Traditions of the British School of Medicine and Its Development." The Revilliod-Julliard lectures were founded four years ago for the purpose of perpetuating the names of Dr. Léon Revilliod and Dr. Gustave Julliard, formerly professors of clinical medicine and clinical surgery, respectively, at the Faculty of Medicine. The lecturers must be men of eminence of other countries, although well known men in the Swiss profession are not excluded. The lectures must be delivered in French and all branches of science directly pertaining to medicine or surgery are treated. This lectureship has been founded upon quite the same lines as those of the Royal College of Physicians or Royal College of Surgeons of London.

The Emperor Frederick Controversy Revived.—An interesting contribution to the history of the tragedy of the Emperor Frederick has recently appeared in the memoirs of Prof. Wilhelm von Waldeyer, the well-known anatomist. Apart from its general interest to the reading public, the book will doubtless be of some little interest to the medical world. The author was one of those consulted at the time when doubt still obtained as to whether the malady of the then Crown Prince Frederick was cancer or not. In his memoirs Prof. von Waldeyer goes minutely into the examination made by Sir Morell Mackenzie and repeats the statement which he declares was made at the time by Dr. Gerhardt, that the specimen which Sir Morell Mackenzie removed for histological examination was not from an affected part, with the result that Virchow, who made the microscopic examination, found no evidences of malignant change. Von Waldeyer gives a full account of the necropsy and the great formalities with which it was attended. He declares that the result of the autopsy settled once for all that there was an extensive malignant neoplastic formation in the throat, and therewith all legends to the contrary. Throughout the book the author supports the point of view taken by von Bergmann and Gerhardt and opposes that supported by Sir Morell Mackenzie, but the matter is treated apparently in an entirely scientific spirit and is devoid of the political prejudice that has hitherto disfigured every German treatise on the subject.

Tobacco and Infant Mortality.—Some interesting statistics, which have not been given to the medical press, have been tabulated by Grimpret

of Lille, on the mortality of infants born of mothers employed in tobacco factories. The first table is that of infants during the first year of life, breast fed, the mother remaining at home for the first fifteen days to two months and after her return to the factory after the lapse of this time, the infant being bottle-fed. Of these, the percentage of mortality was 9.67 per cent. Mortality of infants breast-fed by the mother at the factory, 11.11 per cent. Infants breast-fed for fifteen days to two months at home and then by the mother or bottle at the factory, 15.64 per cent. Infants breast-fed at home for the first fortnight to two months and this continued for fifteen days to six months after the mother's return to the factory and followed with the bottle, 24.61 per cent. Infants fed by bottle in their families or by servants, 35.65 per cent., and lastly, breast-fed infants whose mothers did not return to factory, 38.77 per cent. The largest mortality therefore is among infants whose mothers nurse them for a time at home and then return to the factory with them, where nursing is continued with either the breast or bottle, those brought up on the bottle at home by members of their family and those breast-fed at home, the mother not returning with them to work. A figure that may seem paradoxical is the percentage of deaths in infants breast-fed, the mother not returning to work. It is the highest of all, contrary to what should take place, especially if tobacco had any influence on the maternal milk. But it is clear from an examination of the statistics presented by Grimpret that tobacco does not appear to exercise the slightest influence on the maternal milk. The analyses made by Gérard likewise bear this statement out. Grimpret also shows that tobacco has no injurious action on the pregnancy, but it is evident that the mortality during the first year of life in infants born of women working in tobacco factories is fairly large and largely due to cerebral affections, especially in bottle-fed babies, but tobacco cannot be held responsible for this.

3. Sympathy in Medicine. J. M. Pottinger.
4. Cases in which Basal Metabolism Measurement Is Useful. Oliver H. Stansfield.

2. Clinical Observations with Benedict's New Portable Respiration Apparatus.—Paul Roth holds that this apparatus gives most satisfactory results in its use for the estimation of the basal metabolic rate, and of vital capacity. Its adaptability and reliability are demonstrated by a series of observations on a large number of unselected clinical cases of all types, as well as on both trained and untrained subjects. Comparisons with more elaborate methods emphasize its simplicity and practicability in clinical work.

1. The Classical Endocrine Syndromes.—Lewellys F. Barker discusses the thyroid syndromes, the parathyroid syndromes, the thymus gland syndromes, the hypophyseal syndromes, the pineal syndromes, the suprarenal syndromes, the gonadal syndromes, and the climacteric syndromes, all now fairly well established as of endocrine origin. The general practitioner who will familiarize himself with this small group of syndromes and will afterwards analyze the cases that present themselves to him for study from the viewpoint of these, will find it easier, later, to analyze the more complex cases in which more than one gland of internal secretion is markedly disturbed (multiglandular syndromes). For this reason the writer has not included in his discussion the Timme syndrome, the thyrotoxic hypophyseal syndromes, the thyrotoxic suprarenal syndromes, or the several forms of infantilism.

10. Does the Pituitary Secretion Influence the Development of the Prostate?—Hans Lissner presents the histories of five cases of preadolescent hypopituitary infantilism, two of the Fröhlich, and three of the Levi-Lorain types—all boys. Their ages are ten, fourteen, fifteen, and eighteen. Their corresponding mental ages are three, three, seven, nine and eight. Three boys showed complete absence of the prostate so far as could be determined by rectal examination. The other two revealed a very diminutive prostate. This would seem to be a new clinical observation. It would suggest that the normal development of the prostate is in part, at least, dependent on normal pituitary secretion.

11. Dissociation of Microbic Species: A Preliminary Communication. Paul H. De Kruif.

3. The Necessity for Clear Thinking in Milk Modification.—Lewis Webb Hill considers it vital for every general practitioner to have a good working knowledge of infant feeding, embracing: (1) How to dilute or combine milk or cream in such a way as to secure any desired combination of quantities of the three food elements (fat, sugar, and protein), in the resulting mixture. (2) The pathogenesis and nature of the various digestive and nutritional disturbances of babies. (3) A knowledge of what combinations of the food elements are suitable for any particular baby, sick or well. The practitioner must have clearly fixed in his mind the elementary nature of milk; he must not look on milk as milk, but he must look on it as being made up of fat, sugar, protein, salts and water. He must realize that disturbances of digestion arise from sugar, from fat, or from protein or from improper combinations of these elements, and that, therefore, he must take into account the amounts of these that he is feed-

ing to any baby, and be able to vary each one of them at will in any mixture he offers. He must also have some numerical method of expressing these amounts. The three methods of milk modification now in general use are: (1) whole milk dilution; (2) top milk (cream) dilution, and (3) gravity cream and skimmed milk mixtures. It is not of great importance which of the modifications is used, provided the physician gives enough food in total quantity and the proper combination of the individual food elements to suit the digestion of the baby he is dealing with, and that he knows approximately the amount of each food element in the mixture, in order that he may vary these quantities at will, that he may be able to proceed in a rational manner, and that he may be able to express clearly to others, in the exact language of figures, what he has done. The modification of milk is the mechanical part of infant feeding. It is not the calculation that is difficult—any inexperienced medical student can quickly learn milk modification and calculation; the part of infant feeding that is difficult, that requires judgment and experience, that often eludes many, in spite of years of experience with many babies, is *knowing when to feed what*.

6. Studies of the Nasopharyngeal Secretions from Influenza Patients.—Oltitzky and Gates, in this preliminary report on cultivation experiments, record in brief detail these experiments and their results. From the filtered nasopharyngeal washings from early cases of uncomplicated epidemic influenza and from the lung tissues of experimental animals, they cultivated minute bodies of characteristic morphology which are strictly anaerobic, are filtrable, and withstand glycerolization for a period of months. The effects on the blood and in the lungs of rabbits and guinea-pigs injected with these bodies are similar to those produced by the filtered and unfiltered nasopharyngeal secretions from early cases of epidemic influenza.

8. Stereoscopic Roentgenography.—H. D'Arcy Power holds that most conditions requiring examination in this way can be included within the dimensions of a 3 by 4 plate, and two such plates taken under a tube, with a difference of 2½ inches from their centers, could be examined in an ordinary stereoscope. In most cases in which this is done, the area to be examined stereoscopically would be determined first by the fluoroscope, or a single exposure on a large plate. Besides giving a better basis of judgment for the position of foreign bodies, this procedure has a field in determining the direction of anal and other fistulas, and in the visualization of the eyelid for the better localization of small foreign bodies in the eye.

6. The Work of the Metropolitan Asylums Board for the Mentally Defective. The Very Rev. Canon Sprankling.

1. A Record of Seventy-six Cases of Uterine Fibroids and Chronic Metritis Treated by X-Rays.—Eden and Provis base this contribution on forty-six cases of uterine fibroid tumors and thirty cases of chronic metritis treated with x-rays during the years 1914-1920 inclusive. Three of the patients have died from independent causes since treatment, and the writers have been able to obtain reports as to the present condition of all but fourteen cases, at intervals varying from three months to six years after the treatment. Of the forty-six cases of fibroid tumor thirty were married, fifteen were single; of the thirty cases of chronic metritis twenty-five were married, five were single. Eight patients were between thirty-six and thirty-nine inclusive, the remainder from forty to fifty-six inclusive; the proportion of cases below forty was therefore small—about ten per cent. The points which bear upon the selection of cases for x-ray treatment are: (1) age of patient, (2) size of tumor (if a fibroid), (3) character of hemorrhage, (4) degree of

anemia, (5) presence of complications, such as inflammatory disease of the appendages, degeneration of a fibroid tumor, etc. The cases are epitomized, and the following conclusions drawn: 1. X-ray treatment should be regarded as the method of choice in women over thirty-eight for all uncomplicated cases of severe hemorrhage due to chronic metritis, or other conditions in which no neoplasm is present. These cases yield more readily to the treatment than do fibroid tumors. The presence of inflammatory disease of the tubes and ovaries is contraindicated. 2. Fibroids of the size not exceeding the height of the umbilicus may be treated with x-rays if the patient is over thirty-eight years old, if the hemorrhage is of the regular monthly type, and if there is no evidence of inflammatory disease of the tubes and ovaries, or of advanced degenerative changes in the tumor. If intercurrent conditions which tend to increase operative risks are present x-ray treatment should be regarded as the method of choice, in other cases the choice may usually be left to the patient.

2. Operation for the Removal of the Appendix in the Quiet Period.—W. H. Battle gives an analysis of the conditions found in the abdomen after one or more attacks of appendicitis in one thousand cases operated on by him or by a house surgeon under his supervision. At each operation the parts around were also examined, adhesions estimated and treated, and the pelvic organs examined for abnormality, displacement, or disease. The state of the appendix in the thousand cases of removal in the quiet period was: apparently normal, 7; hypertrophy, 1; obliterative inflammation, 16; catarrhal, 511; stricture, 317; after abscess, 145; tubercle, 2; carcinoma, 1. In the first four hundred cases there was one death caused by accidental infection of the peritoneum by the *Bacillus pyogenes aureus*. In the additional six hundred there was one death, the result of vomiting and giving way of sutures in a stout flabby woman of fifty-six. In this case there was a partial excision of the cecum. In only one of the series did a complete hernia develop. This occurred in a fat agricultural laborer who had much vomiting after operation. In his case the abdominal wall was successfully repaired. In two others there was a weakness of the scar, probably due to the yielding of sutures in the posterior sheath as a result of vomiting, but no bandage (or truss) is required. If the appendix has been cleanly removed at its junction with the cecum, and there is no other abnormal state of the abdominal organs which has been overlooked, the prognosis as to complete recovery is very good. The attacks of pain will cease and he may expect to resume work within a month. Where the proper precautions are observed at operation there is no likelihood of adhesions forming later, but the prognosis in those cases where adhesions had already formed as a result of previous attacks is less certain, but often these do not produce symptoms. The time lost from the working years of the individual cannot be easily calculated; several had become chronic invalids. The patient who has had an undoubted attack of appendicitis is acting wisely to get rid of the probable source of future trouble.

7. The Herpes-Varicella Infection. A. E. Carver.

2. Diathermy in Diseases of the Nose and Throat.—W. J. Harrison states the advantages of this method of treatment as follows: Shock is practically nil, even after extensive operations. Pain after the operation is less than after operation by knife or cautery. Temperature is only slightly if at all raised, rarely reaches 100 degrees, and drops within forty-eight hours. The dangers of metastases are much less than with cutting operations, blood vessels and lymphatics being sealed.

Risk of septic absorption is less than in any other form of operation. There is complete destruction of visible and palpable malignant disease, and probably many outlying cells are destroyed which could not otherwise be reached. Malignant cells are of lower vitality than those of healthy tissue. The operation is practically bloodless, is rapidly and easily performed, and can be easily repeated if necessary. Tumors that are otherwise inoperable can be attacked. Convalescence is rapid. In many cases which are hopeless, relief can be given to the patient. The disadvantages are as follows: Healthy and diseased tissues are destroyed, but in cutting operations this also takes place. Important vessels and nerves cannot be seen. There is danger of secondary hemorrhage when working near large blood vessels. There is a tendency to the formation of keloid when skin surfaces are involved.

4. The Treatment of Uterine Hemorrhage Not Associated with Pregnancy.—James Phillips thinks there can be little doubt that in all cases which come within this discussion, whether an obvious lesion of the uterine wall or of its lining membrane exists or not, the essential cause of the bleeding is an abnormality in the internal secretions. Some day one will learn how to regulate the functioning of these substances, but in the meantime, whenever the bleeding is so severe and so persistent as to make the patient's life a burden, the only certain means of curing her is to remove the uterus. Packing the vagina, curettage, ergot and similar drugs are most uncertain remedies and at best produce only temporary improvement. For beyond a doubt the patients who consult their doctors about bleeding of this sort as a rule never feel well; apart altogether from the hemorrhage there are symptoms, none of them perhaps very bad, but in the aggregate producing a sense of illness enough to make most women willing to risk operation in order to get rid of it, if they are not definitely discouraged by their medical attendant.

5. Some Deductions from the Statistics on the Prevention of Pulmonary Tuberculosis.—H. C. Given holds that the campaign against consumption must be directed against the air-borne diseases as a whole, and against the common cold in particular. The effect of other respiratory infections, including the common cold and zymotic diseases, in early life is to prepare the soil for the later invasions of the tubercle bacillus when otherwise resistance should be high. The remedy for all these diseases is a matter of improved housing and education in ventilation and general hygiene, yet at the same time much could be done meanwhile by the more thorough recognition and treatment of the common cold and its sequelae.

5. The Nut. T. J. Dimitry.

1. The Medical Treatment of Gall-Bladder Diseases versus Surgical.—A. L. Levin discusses the method of tapping the bile exit region in the duodenum, holding that it will solve the problem to a great extent. It is advisable in any case with a history of gall-bladder trouble, that a duodenal tap should be made from a diagnostic standpoint. If one wants to ascertain the presence of bacteria, besides the color and consistency of bile, he can follow the method outlined by Lyon. The necessary articles are sterilized, the nose is sprayed with Dobell's solution, the throat should be gargled with potassium permanganate (1 gr. to the oz.), the stomach is washed with antiseptics and then the duodenal intubation follows. The writer has modified the procedure and uses his own so-called driving-in and massage method. It is not necessary to give the patient a quantity of water to drink when the tube is introduced, for it is not the water the drives in the tube, but the muscular contractions of the stomach;

he therefore stimulates muscular contraction. Putting the patient first on his back and massaging the stomach region from the cardia towards the pylorus, the gall-bladder region is then massaged, the patient being instructed at the same time to take deep inspirations. The patient is then turned on the right side, the tube hangs over the edge of the bed, and the contents are allowed to escape. The introduction of water by the syringe retards the flow of duodenal contents and bile because it drives the current backwards. It is not always necessary to use magnesium sulphate; sodium sulphate will accomplish the same purpose. If the flow does not start shortly, the method of massage is repeated, the patient being given half a glass of hot water to drink, and instructed to take deep inspirations. The tube is introduced through the nose. The writer's tube has a velvet eye, the openings are oval and larger than in the Jutte tube, there is no metal bucket to cause irritation and the quality of the rubber is such that there is no need for a stylet. Patients who do not improve in spite of persistent treatment should be referred to the surgeon for a more radical treatment. This in itself is a point of diagnostic importance.

1. Climate in Relation to the Treatment of Tuberculosis. Edwin P. Kolb.
2. An Address on Phthisis Pulmonalis. Albert C. Gevser.
3. A Further Consideration of Intestinal Fistula Following Appendicitis. James C. Kennedy.
3. A Further Consideration of Intestinal Fistula Following Appendicitis.—James C. Kennedy, after investigating the statistical reports of several large hospitals in Greater New York, found the mortality in appendicitis to be about sixteen per cent. The cases in which mortality was found were principally those of general peritonitis, suppurative peritonitis, and case moribund on admission. From his own late experience in hospital wards, and from inquiries made among surgeons, he finds that conditions have not materially changed since this investigation, made some time ago. In this connection the writer condemns the prolonged use of the icebag, and directs attention to intestinal fistula as one of dangerous sequelae of appendicitis. He believes that the cause most potent in the production of this particular class of fistula is neglect of the rule: "Operate as soon after the diagnosis of acute infective appendicitis is made, if the disease is progressive." In his experience early operation is not only wise conservatism and life saving, but the surest means of preventing intestinal fistula following appendicitis. The points especially emphasized, in addition to early diagnosis and early operation if the disease is progressive, are the following: In so-called fulminating and late cases study well the pathology of the caecum and the adjacent tissues about the appendical base. If bacteria have necrosed the tissues about the appendical base excise the stump and treat the rent as in gastric ulcer, placing a Mikulicz drain over the Lembert sutures, provided the patient's condition will permit the work. In obstinate fecal fistula following appendicitis, practically when producing an artificial anus, not only rendering patients helpless, but endangering their lives, resect the cecum and anastomose the small intestine laterally with the cecum. As a large proportion of fecal fistulae following appendicitis close spontaneously, unless of the dangerous variety requiring immediate attention, one should wait from three to five months for this spontaneous cure.

Morgan's Bacillus.—Besson and de Levergne have found a new bacillus in the summer diarrhoea of children which seems to be able to set up a dysenteric syndrome. It may be distinguished from the paratyphus B. in that it does not ferment mannite, but does form indol in abundance. The endotoxin is able to set up in the rabbit hemorrhagic lesions in the small intestine which appear to be identical with the alterations of Peyer's patches in human typhoid. Whatever its relations with paratyphoid bacilli the new organism is quite separate from the dysenteric microorganisms.—*La Presse Médicale.*

Book Reviews.

THE ENDOCRINES. By SAMUEL WYLLIS BANDLER, A.B., M.D., F.A.C.S., Professor of Gynecology in the New York Post-Graduate Medical School and Hospital, Philadelphia and London: W. B. Saunders Company, 1920.

THE author of this interesting book has attempted the difficult and somewhat dangerous task of making a permanent record of the knowledge thus far acquired in a rapidly progressing science. The accomplishment of such a feat requires a prescience on the part of the writer which few possess. Prophecy is risky and we dare not say whether the book before us has so far anticipated the future of endocrinology as to hold its place for a time as a reliable expositor of this new science, or whether it will, like so many articles on the subject in the periodical literature, soon be out of date. We are inclined to believe it will survive, but whether it does or not, it is a book of great present value, entertainingly written, easy to read, and full of the latest knowledge which the busy workers in endocrinology have brought to light.

The first two chapters deal with animal instincts and with the action of heredity and environment upon the character of the child. Then follows a chapter entitled, "An Introduction to the Story of the Endocrines," and this is succeeded by chapters describing in more or less detail the physiological action of the various internal secretions, the disturbances caused by changes in them, the influence of these secretions upon conduct and upon health, and the therapeutic uses of the endocrines. Not the least interesting and instructive section of the book is that on clinics and cases in the two closing chapters.

The author of this work is a gynecologist and in his application of the endocrine theories he lays particular stress upon the influence of the secretions upon the reproductive functions of woman, but their general relations are not neglected, and we know of no book in which the inquirer after endocrine knowledge can find a more satisfactory answer to his quest.

OCCUPATIONAL AFFECTIONS OF THE SKIN. Their Prevention and Treatment with an Account of the Trade Processes and Agents which Give Rise to Them. By R. PROSSER WHITE, M.D. Ed., M.R.C.S. Lond., Life Vice-President, Dermatologist, Senior Physician and Ethnethic Officer, Royal Albert Edward Infirmary, Wigan; Vice-President Association Factory Surgeons; Life Fellow London Dermatologists' Society; Member Manchester Medical and Dermatologists' Societies; Hon. Life Member St. John Ambulance Association; Associate Editor, *Journal of Industrial Hygiene*; S.M.O. and Cadet Colonel Church Lads' Brigade. Second Edition, with twenty-four plates (comprising twenty-eight figures). New York: Paul B. Hoeber.

ONLY those affections of the skin are considered that depend for their origin upon physical trauma. Certain general topics such as nomenclature, prevalence, resistance of the skin, pathology, predisposing causes, idiosyncrasy, and internal causes of toxicoderma are presented in the first chapter under the general heading of "A Circumspection." In the second chapter, called "A Conspectus," items dealing more directly with the type and character of skin eruptions are discussed, leading to a grouping based on "Agency" or occupation. As in the grouping of all medical entities, so in the grouping of dermatopathies, there are to be expected merits and demerits. The grouping on the score of agency has the merit of being inclusive, but has the demerit of permitting frequent overlapping. Doctor White describes many of the known skin eruptions, indicating the particular industry in which they are likely to be found injurious. These are grouped on the basis of agency, nine groupings being presented, including physical agents, acids, alkalies and some metal salts; the dust eruptions; industries; occupations; trades; synthetic dyes and dyeing; plant poisons; and vital agencies. Each group is considered in a separate chapter in which there is discussed for each condition under the group what phase of industry is conducive to the production of the dermatitis, factors that must be recognized to preclude its occurrence, and

a description of the pathological characteristics of the dermatitis. Occasional general indications for treatment are outlined, though the therapeutic considerations are extremely brief, and for many conditions not at all discussed. Numerous selected references are supplied, and such figures as appear are clear and entirely illustrative of the condition represented.

INNERE SEKRETION UND DEMENTIA PRÆCOX. Eine Studie von OSCAR LESSING, Dr. Med. et. phil., Arzt in Berlin. Berlin: S. Karger, 1921.

IN this brief but thoroughly conscientious work, the author admirably reviews and correlates facts of endocrinological significance with the psychic, physical, and biochemical characteristics of dementia præcox. The significance of the temporal relation between the onset of the disease and the endocrine revolution of puberty; the Abderhalden reactions in dementia præcox for endocrine proteins; the interpretations of the changes in the skin and pupil of dementia præcox on an endocrine basis; the reactions of these patients to adrenalin, atropine, pilocarpine, and the therapeutic results obtained in these cases by the use of endocrine extracts are reviewed in a most interesting fashion.

Although the author does not report any original work, the volume will prove of interest to the internist as well as to the psychiatrist, inasmuch as it goes far in establishing the fact that among the psychopathies, dementia præcox is not a disease of the brain alone, but a generalized constitutional abnormality due to endocrine imbalance which always has a profound and far reaching significance.

A LABORATORY MANUAL OF ORGANIC CHEMISTRY FOR MEDICAL STUDENTS. By MATTHEW STEEL, Ph.D., Professor of Organic Chemistry and Biological Chemistry, the Long Island College Hospital, Brooklyn, N. Y. Second edition. New York: John Wiley & Sons, Inc., 1920.

THIS manual began life as a laboratory guide and has had a successful existence. The experiments presented are comparatively few, but are carefully chosen so as to illustrate principles. As a rule definite quantities of chemicals are specified in the directions, an excellent practice. In this new edition there is added a chapter on the Colloidal State that should prove very valuable. Colloids play such an important part in medical chemistry that a working knowledge of them is essential to the physician and the subject is rarely presented adequately. The book is printed with the alternate pages blank so that the student may conveniently elaborate the notes and fill in the equations. It is an attractive book.

GEBURTSHILFELICHES VADEMECUM. Ein kurzes Lehrbuch der Geburtshilfe für Studierende und Aerzte. Von Prof. Dr. A. DÜRRSEN in Berlin. Dreizehnte bis fünfzehnte Auflage. Berlin: S. Karger, 1921.

THE first edition of this little manual appeared in 1890 and the eleventh-twelfth in 1919. In the brief preface to the present edition the author states that it in part memorializes the twenty-fifth anniversary of the publication of his original operation of vaginal cesarean section. The description of this procedure is rewritten with new illustrations. It is mentioned no less than ten times in the course of the book, in its various indications.

THERAPEUTISCHES VADEMECUM FÜR DIE KINDERPRAXIS. Von Dr. HANS KLEINSCHMIDT, Professor der Kinderheilkunde an der Universität, Hamburg. Zweite und dritte verbesserte Auflage. Berlin: S. Karger, 1920.

THIS little manual appeared originally in 1918 and the edition was exhausted within the first year. There was no occasion, therefore, for notable alterations, but the author has given the book the benefit of the criticisms as well as added material which appeared to him desirable. The earlier chapters are devoted to nutrition and its disorders, after which the various local affections are serially discussed. Infectious diseases follow metabolic and hemic affections and are followed by affections of the nervous system, this series making up about one-third of the book. There is a supplement on the preparation of food, the book comprising diseases of the newborn and nursing.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held November 16, 1920.

DR. CARY EGGLESTON IN THE CHAIR.

The program of the meeting was contributed by the Staff of the Presbyterian Hospital.

Chemistry and Clinical Significance of Urobilin.—Dr. L. BAUMAN made this presentation, which he summarized by stating that considerable evidence was at hand to show that urobilin was derived from bilirubin as a result of the action of the intestinal bacteria. The results of about 100 determinations of the urine and stool were submitted. It was found that urobilin was increased in pernicious anemia and in disease of the liver. Dr. Bauman showed that urobilin estimations were of value as an aid in the differential diagnosis of primary from secondary anemia.

Dr. JOSEPH C. ROPER said one question in connection with the urobilinogen and urobilin was very fascinating and that was in what form these substances occurred in the blood. He did not think anyone had reported finding them in the blood except in pernicious anemia and in a few cases of pneumonia, reported by Dr. Conner and Dr. Roper, and in those cases at autopsy a focal necrosis was found in the liver. That brought up the question as to whether the liver lesion had anything to do with the change in reabsorbed bilirubin to urobilin. If these substances got into the blood it was in a changed form, and some one was going to find out in just what form it occurred in the blood before it went to the kidney. The kidney in some measure controlled the passing of bilirubin. Up to a certain concentration of bilirubin in the blood, only urobilin appeared in the urine; above that concentration bilirubin was excreted. Possibly in some similar way the kidney had some part in the change of the colorless substance that came over in the blood to the kidney, and was converted into urobilin.

Dr. A. L. GARBAT asked Dr. Bauman if he had found difficulty in the direct examination of the bile. Would there be any advantage in examining the bile directly, especially in view of the recent work whereby it is possible to obtain larger amounts of bile by the use of magnesium sulphate? At the Lenox Hill Hospital they had treated three or four cases of pernicious anemia by cholesterol injections, but no definite improvement resulted.

Dr. BAUMAN, in closing the discussion, said there was one interesting point in connection with what Dr. Roper had said, namely, that it was rather remarkable that we had been unable to determine the presence of these substances in the blood, and after adding these substances to the blood we could not extract them. To explain this it had been assumed that they had entered into combinations with the proteins and other constituents of the blood. Bilirubin was found in the serum before it occurred in the urine, and some one recently had shown that it only appeared in the urine when it was dialyzable. It seemed that the urobilin entered into some combination with the proteins of the blood. The trouble with the examination of the bile was that we obtained only one specimen and we were interested in the twenty-four hour excretion. Another interesting point was that an increase in urobilin was found in the stools when there was not a corresponding increase in the bile.

The Relationship Between Renal Glycosuria and Diabetes.—Dr. H. RAWLE GEYELIN made this contribution, which consisted of a brief review of five cases of glycosuria, three of which showed some evidence of what was known as renal glycosuria, while the other two were pretty frank cases of this condition. The criteria quite generally accepted today of the condition known as renal glycosuria were: (1) Glycosuria without hyperglycemia; (2) glycosuria excretion almost or entirely independent of carbohydrate intake, and (3) glycosuria without symptoms of diabetes. To these criteria some observers had added a fourth, namely, absence of the development of subsequent diabetes. It was important to consider particularly the first two of these criteria,

and it seemed to him that the details and significance of these criteria could best be brought out by the details in connection with these cases. The first three cases fulfilled most of the criteria of renal glycosuria and the fourth and fifth cases fulfilled all of these criteria. The first case was that of a girl admitted to the hospital two years ago with the history that for 27 months she had had severe abdominal pain localized in the epigastrium, considerable nausea, and for the last six months before admission to the hospital attacks of vomiting. She was suspected of having gastric ulcer. It was learned that she had 0.2 per cent. sugar in the urine without any symptoms of diabetes for five weeks before coming to the hospital. Gastric ulcer was ruled out, though the gastric symptoms were not accounted for. During the past six months she had lost five pounds in weight. She had now been under observation for two years, returning to the hospital at frequent intervals. On one occasion the blood sugar rose to 122, but it had averaged 85, and sugar was not present in the urine all the time. Again sugar would be present in the urine every day for one or two weeks irrespective of diet, which apparently had no influence on the glycosuria. She was discharged from the hospital in a fair state of health; although she complained of occasional attacks of abdominal pain, they probably did not amount to much, as she was able to work eight hours a day and held her weight. The second case was rather unusual in that sugar (1.1 per cent.) had been found in the urine nine years ago. This patient was admitted to the hospital in 1917 with the diagnosis of old poliomyelitis, which occurred at the age of two years. Glycosuria had been found in the mother six months before the birth of this child. That condition still continued, there being from 1 to 5 per cent. sugar in the urine all the time. The boy developed glycosuria when six years of age, with some symptoms of diabetes, polyuria, and loss of weight (six pounds in two weeks). Though put on an antidiabetic diet, he did not during his three weeks' stay in the hospital become sugar free at any time. He had been coming back to the hospital for a number of small orthopedic operations since that time, and sometimes there was sugar in the urine and sometimes not. The blood sugar was estimated a number of times, but was never over 120, even following the ingestion of glucose. On a diet containing 350 grams of carbohydrates a day, which was all his stomach could stand, only a small trace of sugar was found in the urine, 1.1 per cent. He was in good health at the present time except for the deformities incident to his poliomyelitis. The third patient developed symptoms of diabetes 18 months ago, as evidenced by loss of weight, increased thirst, not marked, and a considerable itching of the skin, though she did not void large quantities of urine. The urine had been examined three months before because of a sinus operation and showed 1 per cent. sugar with considerable acetone and diacetic acid. At the time she came under observation the blood sugar was 108 grams and large amounts of acetone were present in the urine. In a carbohydrate-free diet with fairly large amounts of fat and protein, the glycosuria continued for three months. She weighed all her food carefully for twelve months and then went on a high carbohydrate diet. For as many as eight days she would show no sugar in the urine, and even when taking from 100 to 200 grams of glucose the blood sugar was not more than 108 grams, even when the estimation was made one-half hour after the glucose was given. In both the fourth and fifth cases the onset was without symptoms of any kind, the sugar being discovered accidentally. One of these patients came to the hospital for a mild synovitis and had lost no weight except when an attempt was made to clear up the sugar. This patient showed a constantly low blood sugar, not above 130 after the ingestion of 100 grams of glucose by mouth. The urine had been tested for the past six months and sometimes showed a faint trace of sugar and at other times as much as 1.9 per cent. This patient ate practically what she pleased and did not weigh her food. The last test for blood sugar showed 160 grams one hour after the last meal. Whether that meant that this patient was developing a true diabetes he did not know. The last patient had been under observation three years, and in his case the ingestion of 200 grams of glucose did

not increase the blood sugar. As to the distinction between these two groups, there were mild symptoms of diabetes in the first three, together with an absence of sugar in the urine for perhaps one-half the time they had been under observation. In the second group the urine was at no time free from sugar and they had no symptoms of diabetes. If we recalled our definition and criteria for renal glycosuria, namely, that the glycosuria should be without hyperglycemia, that it should be independent of carbohydrate intake, and that it should be without symptoms of diabetes, and if, as some observers insisted, the glycosuria must be fairly constant and persistent to establish the diagnosis of renal glycosuria, then the first three cases might possibly not be defined as true renal glycosuria in so far as the first criterion was concerned. As to the second criterion, that the sugar must be independent of the carbohydrate intake, that was true of all the cases. The third criterion, the absence of diabetic symptoms, was not fulfilled by the first three cases. In the second and third cases there were mild symptoms of diabetes.

Dr. NELLIS B. FOSTER said that these cases of Dr. Geyelin were of special interest to any of us who were interested in diabetes and generally interesting to all of us. It was not many years ago that glycosurias were all regarded as one complex; now there was a tendency to take out of the chaotic condition one entity after another and to define its limitations. Renal glycosuria was one of these syndromes. Acromegaly was the first to be taken out of the chaos. Dr. Geyelin had given the criteria upon which the diagnosis of renal glycosuria should be made, and there was no discussion upon that point, as there was a general consensus of opinion as to those criteria. The question was what was the change in metabolism that led to glycosuria. One usually explained it as dependent upon the amount of blood sugar. We knew that these cases of renal glycosuria could not be explained on that ground because the blood sugar was normal, and that brought up the question of the state of the sugar in the blood. Was it there simply in solution, or was there some colloidal state, or was it in combination? There were a number of these problems which would probably be solved in our time. Dr. Geyelin's cases were rather unusual in the features they showed clinically, and he was perhaps wise in not expressing a personal opinion as to whether they were all cases of renal glycosuria. In the second case the mother was diabetic and the child also had symptoms suggestive of diabetes. He thought Dr. Geyelin felt that it was questionable whether or not that case represented one of true diabetes. Presumably he was watching that case and only time would reveal its true nature. It was formerly thought that renal glycosuria was a relatively rare disease, but now the number of cases was increasing constantly, and while it was not as common as true diabetes it was not a rare disease. It was most important when glycosuria was discovered to make a differentiation between renal glycosuria and true diabetes, not only because of the prognosis, but because of the burden put on the individual with true diabetes who was forced to live a life of almost intolerable privation compared to the patient with renal glycosuria, in whom deprivation need not necessarily be arduous, and in many cases need not be of any significance whatever.

Dr. A. I. RINGER said that in any discussion of renal glycosuria renal permeability must be taken into consideration. All cases of renal glycosuria were the result of lowered permeability of the kidney for sugar. In the normal kidney with 120 milligrams of sugar in the blood none passed into the urine. In any study of a large number of patients some would be found who had glycosuria with a normal blood sugar. On the other hand he had come across cases showing no glycosuria with a blood sugar of 140, 180, and in one case even 240. At the Montefiore Home, Dr. Bauman and he had studied carbohydrate tolerance in normal individuals and it was surprising how large a number of normal individuals had a blood sugar content of 150 or 160 milligrams per 100 c.c. after sugar ingestion, without any demonstrable trace of sugar in the urine. The whole problem was not so simple as it might seem, and the factor of kidney tolerance or the sugar threshold must be considered. He could readily conceive of

a case of true diabetes with lowered kidney threshold for sugar with glycosuria and low blood sugar. The determining factor, therefore, should not be the blood sugar alone.

Dr. JACOB DINER said Dr. Foster had mentioned a very important feature which deserved emphasis. The patient as well as the disease was to be considered. It was (almost) a verdict of incurability to tell a patient he was suffering from diabetes. It was not only the privation in reference to diet that made the unfavorable impression on the patient, but especially the feeling that he was suffering from an incurable condition, so it was very desirable that we should be able to make a differential diagnosis and determine whether we were dealing with a case of true diabetes or one of renal glycosuria. Sugar in the urine was (perhaps) not as important as the other criteria in differentiating these conditions.

Dr. A. A. EPSTEIN said that he wished he could feel as confident as did Dr. Geyelin and Dr. Foster of the value of the criteria established for differentiating renal glycosuria from true diabetes. It seemed as though an effort was being made to fit cases to a prescribed standard and call them by the name of a condition which perhaps did not exist. He would consider the first three of the five cases presented by Dr. Geyelin as instances of mild diabetes. Dr. Geyelin's own supplementary remarks seemed to concede this point. He (Dr. Geyelin) further admitted that the fourth case (i. e. the first case in the second group) was possibly a case of true diabetes, so that, of the five cases presented, only one appeared to answer the conditions put down for renal diabetes. It seemed that the only basic point of difference between renal and true diabetes was that of a normal or subnormal percentile blood sugar content. This was not a sufficient criterion. As had been shown by Dr. Epstein and confirmed by Woodjatt, the blood volume in diabetics varied sometimes from hour to hour and day to day, and any determination of the blood sugar content was not a true measure of the amount of sugar circulating in the blood. Hyperglycemia as defined by Epstein and Baehr (definition apparently accepted by Joslin) was an increase in the total amount of sugar in the blood in circulation. Therefore, a simple percentile estimation did not take into consideration whether the blood volume was increased or not, and hence, whether the blood was concentrated or diluted; it thus failed to show whether or not a hyperglycemia was present. As for the other criteria, chief of which was the assertion that carbohydrate intake did not influence the sugar excretion, it might be said that there were mild cases of diabetes that behaved in the same way. Dr. Epstein cited a case of a pregnant woman who was a true diabetic and who in the later stages of the pregnancy showed no hyperglycemia. This change in the percentile sugar content was found to be due to an increase in the blood volume, which so altered the sugar concentration of the blood as to mask the hyperglycemia. Had the blood volume been disregarded in this case it might have been classed as a case of renal glycosuria.

Dr. EUGENE F. DuBois asked Dr. Geyelin if he had made any determinations of the respiratory quotient and if he had found whether the patients were drawing from their own carbohydrates a large percentage of their calories. In glycosuria a patient might derive 80 to 90 per cent. of his calories from his own carbohydrates.

Dr. GEYELIN said he had not observed any case showing a picture such as these patients presented for a longer period than Case II, which was observed for nine years. The remaining cases reported this evening and 18 others had been observed for shorter periods, but they had shown no symptoms that led him to believe they were becoming cases of true diabetes. The case with the recent high blood sugar was the only one that might be developing a true diabetes. In reply to Dr. DuBois's question as to whether he had determined the respiratory quotient, and whether the patients were drawing from their own carbohydrates a large percentage of their calories, such determination was made in Cases I and IV, and the respiratory quotients were found to be 82 and 84 respectively, showing that the patients still had the ability to oxidize carbohydrate. In reply to Dr. Epstein, if one took cases of true dia-

betes as a standard and compared these cases with them, in practically 90 per cent. of the criteria these cases did not fit in with the picture of true diabetes. He could not see how by any stretch of the imagination one could class these cases as cases of true diabetes. One had to take into consideration not only the laboratory findings but the clinical course and the symptoms. As Dr. Foster had said, we did not want to bind ourselves down to a hidebound definition. It might be that these cases would eventually develop into true diabetes.

Observations on Streptolysin.—Dr. FRANKLIN A. STEVENS presented this contribution. He said that the object in studying hemolysin production was to gain some definite knowledge concerning the much mooted question of the relation of streptolysin to the virulence of streptococci. Since the original observations of Marmorek and Schottmüller, various workers had reached contradictory opinions concerning this relationship. Some had maintained that there was no relationship and others held that the more virulent streptococci produced greater hemolysis. There were two methods by which observations might be carried out—by plate cultures and by cultures in liquid media. Plates, necessarily, on account of the number of factors which entered into their composition, gave very indefinite results. The only method by which we could definitely determine the maximum concentration of lytic substances was by the study of liquid broth cultures. It was found that the maximum concentration might be reached at different times during the growth of hemolytic streptococci. Determinations made at any set time or an average of the determinations made during the growth were unreliable. The variations which occurred might be due to inherent properties of the streptococci themselves, to environment in which they were grown, or to passing changes which had been induced by animal passages. The inherent properties might be shown on plates, according to the original classification of Schottmüller. The second type of variation, due to the presence of various substances in the media, might be well demonstrated by the action of fermentable carbohydrates, which presumably lessened the lysis production by reason of their protein sparing action. The acid produced also lessened the action of the lysis on red cells. Sera from different animals also caused variations, but these might be obviated by increasing the amount of serum in the media or by adding large amounts of peptone. Variations in the time of production might be caused by increasing the virulence of streptococci by animal passage. If mouse virulent strains were compared with avirulent strains in horse serum media, the avirulent strain grew more rapidly and the maximum streptolysin concentration was reached at an earlier time during the growth of the cultures. The concentrations reached by both strains were constant. The variations were probably due to the variations in the protein content of the media and to the avidity with which the protein was attacked.

Dr. LIBMAN said that he was very glad that Dr. Stevens had taken up the subject with accurate methods. It was one in which he had been interested for many years, since the question of hemolysis was important practically in clinical and pathological work. It was important to remember that the clear-area around the colonies did not always mean hemolysis. At times it was probably really a hemoglobinopoeia. Dr. Libman said that many years ago he had described a concentric clearing around colonies of pneumococci and streptococci. He was in the habit of calling the appearance in the plate "clearing," and not hemolysis. Dr. Stevens had drawn attention to the fact that had been commented upon by a number of observers that an organism which produced clearing on a medium might fail to produce clearing if a fermented carbohydrate was present. One reason for this was that when bacteria were grown first on carbohydrate medium, they used up the carbohydrate first produced and lost properties which they ordinarily possessed. Bacteria grown on sugar medium might lose the ability to produce pigment, odor, or proteolysis. Color production might also be interfered with, as shown by the fact that the pyocyanous bacillus, when grown on a medium containing ascitic fluid and two per cent. glucose, gave a white instead of a green growth. Apart

from this interference with the usual properties of the streptococcus, the clear area might be obscured by the presence of precipitation. Dr. Libman said it was important to know that an anhemolytic streptococcus could produce clearing in blood plates made from the blood of the patient from whom the organism had been recovered, but that one could prove that the organism was not a hemolytic streptococcus because the same organism would not produce clearing in the blood of other human beings or of animals. As a rule there was no difficulty in regard to this point, because a *Streptococcus hemolyticus* usually caused clearing as soon as the organism began to grow, whereas an anhemolytic streptococcus, that had temporarily acquired this power, usually did not produce clearing within the first twenty-four hours of the growth of the organism. It had been found in 1907 by Drs. Buerger and Ryttenberg that pneumococci could, in the human body, lose some of the characteristics that distinguished them from streptococci. Later studies had shown that hemolytic streptococci could, under certain conditions, lose the power of producing clear areas on blood plates.

Dr. STEVENS, in closing the discussion, said there were several points which he did not bring out in the original paper concerning the relationship of hemolysin to the presence of sugar in the media. Dr. Libman had just mentioned some of these. The presence of fermentable sugar in plates acted largely through the presence of the acid produced in the destruction and utilization of the carbohydrates. It inhibited the cocci and caused the rapid disintegration of the hemolysin. In addition there was a marked discoloration of the plate due to the action of the acid on the hemoglobin. It was, however, questionable whether there was any action similar to the action of living pneumococci on red cells previously described by Dr. Cole. In determining the classes of streptococci depending on the active production of hemolysin, the most reliable test was the test tube method, which was recommended by the army during the war.

The Interrelations of Precipitins, Precipitinogen, and Symptoms in Serum Disease.—Dr. GEORGE M. MACKENZIE made this contribution, based on studies carried out in collaboration with Dr. Warfield T. Longcope and Dr. Leake. He stated that two years ago one of the authors and Rackmann reported observations on the precipitin, anaphylactic antibody, and cutaneous hypersensitivity in individuals to whom serum had been administered therapeutically. The present study was undertaken to determine whether or not the disappearance of horse serum from the circulation could be brought into relation with the precipitin formation or the symptoms. By the technique described in detail in the paper, serum disease was studied in 21 patients to whom anti-pneumococcus or anti-meningococcus serum was administered either intravenously or intraspinally in amounts varying from 34 c.c. to 630 c.c. Because of complicating factors two of these patients were excluded from the analysis. Of the 19 patients remaining, varying in age from 13 to 56 years, 14 were males and 7 females. Eighteen were patients with lobar pneumonia Type 1; one was a patient with meningococcus meningitis. The results of the analysis of this series of patients showed that from the point of view of circulating precipitin, persistence of precipitinogen, and severity of symptoms they could be divided into three groups: (1) Eleven of them were distinctly of one type. These were the good precipitin formers who had severe serum disease and got rid of precipitinogen soon after the symptoms had subsided. (2) A group of four patients contrasting sharply with those of the first group. They were poor precipitin formers, had little or no serum disease, and retained the precipitinogen in the circulation for many weeks, and perhaps months. (3) Of the remaining four patients, three presented more or less distinctly intermediate forms, and the case of a single patient in whom the results seemed at variance with the observations on the other eighteen might perhaps be explained by a technical error. After a detailed analysis of these three groups of patients charts were exhibited showing the precipitin and precipitinogen curves, and attention was called to the wide variations in the reactions of individuals to the administration of foreign proteins.

Dr. HANS ZINSSER said that the lateness of the hour

would make it quite impossible for him to discuss Dr. MacKenzie's paper with the care that it deserved. The work had a theoretical importance which was considerable, owing to its apparently successful attempt to establish a direct relationship between the appearance of antibodies in the blood of horse-serum injected people, and the development and disappearance of symptoms of serum sickness. The question was involved with the important problem as to whether serum sickness could justly be included with true anaphylactic phenomena. Dr. Zinsser said that it was not necessary to go into the original theory of von Pirquet, as he assumed that everyone present was familiar with it, but that Dr. MacKenzie's experiments seemed to him to furnish very important support of this theory, and tended to confirm the anaphylactic nature of serum disease. In a general way Dr. MacKenzie's observations, he said, corresponded with his own observations in monkeys in which a similar parallelism between antibodies and the appearance of anaphylactic symptoms could be traced. It was quite impossible, however, for anyone to draw analogy between conditions in monkeys and those in man, since it was apparently easy to show antibodies in man after serum injections, whereas, in monkeys, not only were no antibodies formed in some cases, but, as he was able to show by the most delicate anaphylactic method (that was the fallopian tube method of Dale) there was practically no reaction in one monkey tested three weeks after a single injection of horse serum. The presence of antigen and antibodies simultaneously in the blood of Dr. MacKenzie's cases was in keeping with many observations made in animals, and he, personally, as he had expressed in a number of papers previously, believed that one of the fundamental principles of the mechanism in the circulation was the prevention of rapid union between the antigen and antibody in the blood by influences that he believed analogous to the action of protective colloids. It was this mechanism that Dr. Zinsser thought was a sort of emergency safety device which prevented anaphylactic injury by the sudden union of the two substances when simultaneously in the circulation, and which was responsible for the fact that it was unsatisfactory to attempt to prevent anaphylactic shock in animals by injections of anti-serum specific for the antigen. A very interesting phenomenon, he thought, was the speeding up of precipitin formation in the previously injected animals on reinjection, an observation which was entirely analogous to phenomena noticed in many animals when antigen was reinjected after previous immunization. An increased reaction capacity of the cells seemed always to follow a previous immunization with any particular antigen. Dr. Zinsser could find no explanation for one peculiarity in Dr. MacKenzie's curve, namely, the disappearance, at first, of antigen, with later its reappearance in relatively higher concentrations. The only possible explanation he could see for that was that after union there was a certain amount of dissociation under the circumstances of the experiment. Such dissociation of antigen-antibody complexes in the body was not unheard of, but in this particular combination he had never seen it. It must not be forgotten that measurements such as those of Dr. MacKenzie (and, in fact, all antigen-antibody measurements) must necessarily be quite gross, and lacking quantitative delicacy, since there was unquestionably a certain amount of union of antigen and antibody, both *in vitro* and *in vivo*, which took place without visible precipitation. This, naturally, would make it impossible to measure the quantitatively slighter reactions, except perhaps by complement fixation. In reference to the skin reactions which played a part in the testing of sensitiveness of human beings to various proteins, Dr. Zinsser thought that this phase needed a considerable amount of further study, since there were unquestionably two types of such reaction, one, the immediate reaction which occurred following intracutaneous injections, about the specificity of which he felt much uncertainty, and the other the reactions which occurred later on subcutaneous inoculation, which could be regarded as analogous to the so-called Arthus phenomenon, and this latter could be regarded as strikingly specific and of a true anaphylactic nature. There were certain other phenomena in connection with serum

sickness in man, and, in general, reaction to injection which could not be excluded from truly anaphylactic phenomena, the one which occurred to Dr. Zinsser most definitely at that time being one which was called to his attention by Dr. Teague, namely, the reaction which he and everyone else who had ever treated rabies had seen, following repeated injection of rabbit cord into people who had been bitten by rabies-suspected dogs.

Dr. REUBEN OTTENBERG said that on looking over Dr. MacKenzie's charts, it was interesting to note that in two of them the precipitinogen, namely, horse serum, was considerably smaller in amount in the patient's serum on the fifth day than on the tenth, and in one of them examined one day after the injection there was hardly any at all. This raised the interesting question of where the horse serum was during these days before it reappeared in the circulation. The failure to detect it on this case could not be attributed to some sort of balance between antigen and antibody in the patient's blood serum, because the antibody had not yet appeared. A second interesting point was the analogy between the phenomena observed by Dr. MacKenzie of the persistence of precipitinogen in the serum in those cases which formed no antibody, and the persistence of toxins in the circulating blood of such animals as were not susceptible to the toxins and formed no antitoxin for them. For example, it was well established that tetanus antitoxin circulated for an almost indefinite time in the circulation of amphibia which were not susceptible to tetanus and did not form antitoxin.

Stated Meeting, Held December 21, 1920.

DR. CARY EGGLESTON IN THE CHAIR.

This program was presented by the Cardiac Clinic of Bellevue Hospital.

The Roentgen Examination of the Heart with Special Reference to Habitus.—Drs. I. SETH HIRSCH and L. L. SHAPIRO made this contribution, in which they stated that in the Roentgen study of the heart in the light of habitus, the cardiac shadow must be studied in relation to the pulmonary fields in which it was located. The characteristics of the pulmonary fields, namely the altitude, the transverse diameter at the level of the domes, and the degree of curvature of the diaphragmatic domes, were expressions of the habitus. The classification of habitus into four major types, namely, asthenic, hyposthenic, sthenic, and hypersthenic (Mills), was practical and sufficient. Each of these habitus possessed characteristics as regards the transverse diameter, altitude, and basal curve which were peculiar to it. So, also, the changes which were produced in these factors during the respiratory phase were peculiar to the particular habitus. Measurements of the pulmonary fields showed that the altitude had its lowest value in the hypersthenic and its highest in the asthenic. The averages were as follows: Hypersthenic, 22.5; sthenic, 23; hyposthenic, 23.8; asthenic, 23.1. So, also, the transverse diameter reached its lowest value in the asthenic habitus and its highest in the hypersthenic, as follows: Asthenic, 11.6; hyposthenic, 13.2; sthenic, 14.2, and hypersthenic, 14.4. It was interesting to note that the actual measurements of the chest circumference varied in a similar manner with the roentgen measurements of the pulmonary field, the circumference reaching its lowest value in the asthenic and the highest in the hypersthenic, the average being: Asthenic, 70.2; hyposthenic, 78.7; sthenic, 86.9; hypersthenic, 93.2. There existed a distinct variation in the position of the diaphragm with the habitus and an intimate relationship between the position of the diaphragm and the position of the heart. In the hypersthenic, where the diaphragm was high, the heart lay transversely at an angle of 33°. In the sthenic type, the heart lay at an angle of 37°. In the hyposthenic type, the angle of the heart axis was 43°, and in the asthenic the angle was 48° (but might be as much as 55°). It was thus seen that so far as the axis was the expression of position, the heart varied in its site according to habitus. There also was a distinct variation of heart shape with the habitus, especially as regards the convexity of the various curves which constituted the heart silhouette and the value of the auriculoventricular and cardiovascular

lar angles. These were estimated by a new method. The classification of the various cardiac measurements in relationship to age, sex, height, and occupation were of no great practical value. In spite of the fact that these had been computed and recomputed during the last fifteen years, they had not been generally utilized. The only factors which at all played an important part in the practical estimation of the cardiac measurements were the weight, size of the pulmonic field, and value of the obliquity of the heart axis. These were expressions of habitus. On the other hand, an estimation of the values of the cardiac measurements on the basis of habitus showed a distinct association between not only the transverse measurements, but all the other measurements in relationship to habitus. Thus the maximum transverse diameter attained its lowest value in the asthenic and its highest in the hypersthenic, the averages being: Asthenic, 8.8; hyposthenic, 11.1; sthenic, 12.4; hypersthenic, 13.8. So, also, the long diameter attained its maximum value in the hypersthenic and its minimum in the asthenic, the averages being: Asthenic, 11.4; hyposthenic, 13.1; sthenic, 14.1; hypersthenic, 15.9. In studying the relationship of cardiac function to habitus, comparative observations were made as accurately as was possible with regard to the following points: First, the rate and regularity per minute of ventricular contraction; second, the sequence, force, and amplitude roughly of the pulsations of the curves of the right and particularly the left side of the heart. Though not yet prepared to state just what the variations in cardiac function according to habitus were, the writers stated that there was no doubt but that certain types of cardiac function, especially as regards cardiac muscle tone, varied exactly as gastric tone, peristalsis, and mobility varied in the gastrointestinal tract with the habitus. Measurements were made from teleroentgenograms, taken at a target screen distance of seven feet, one inch (216 centimeters), at the level of the sixth thoracic vertebra. The exposures were made in the upright position with the anterior chest wall against and parallel to the plate, taken in full inspiration, except in the asthenic type, where they were taken in complete expiration, and varied from one to three seconds duration. The following measurements were made: (1) Transverse diameter; (2) long diameter; (3) broad diameter; (4) angle of cardiac inclination; (5) width of aortic arch; (6) width of pulmonic fields; (7) length of pulmonic fields, and two new measurements, namely, (8) radius right auricle and (9) radius left ventricle. To obtain the radius of the right auricle three tangents were first drawn to the right auricular curve. Then perpendiculars, drawn from the points where these tangents touched the curve, met at a point which was approximately equidistant from any point in the curve, and a line drawn from this intersection point to any point on the curve constituted a radius. In a similar manner, by drawing tangents and perpendiculars to the left ventricular curve, its radius might be obtained. For each habitus there was a definite radius, which was an expression of the size of the chamber, and varied as the habitus varied and as the heart deviated from the normal. It was thus seen that there was distinct variation of the heart shape according to the habitus. The determination of the early changes in the cardiac outline was of extreme importance because the first indication of a thickening of the walls of the heart or the dilatation of the chambers was manifested by the changes in contour. To this end an estimation of the relative size of the heart chambers could be determined with great accuracy by the determination of the convexity of the curve which constituted the profile of the chamber. By actual measurement the writers had proven that the value of the curve varied with the habitus. These observations warranted the following conclusions: (1) The position of the heart varied with the habitus. (2) The shape of the heart varied with the habitus. (3) That habitus must be taken into consideration in estimating cardiac size. (4) That, reasoning by analogy, the cardiac function, particularly as regards musculature, might perhaps vary with the habitus. (5) That only by actual measurement of the curves of the heart could the change in contour be made out in early cases. (6) That the value of the curves varied with the habitus. (7) That the radial value of the curves of the left ven-

tricle and right auricle varied with the habitus. (8) That the radii measurements were a more accurate and valuable expression of impending or established change in the architecture of the heart chambers than the so-called standard measurements.

Digitalis and the Ambulatory Cardiac.—Dr. E. J. PELLINI presented this communication, in which he asserted that the ambulatory cardiac was a more difficult subject for study than the hospitalized cardiac. In the hospitalized case one had practically all measures always under control, while in the ambulatory case the patient was not merely the subject, but carried out his own treatment as well. The first obstacle encountered was the intelligence of the patients and their lack of appreciation of the importance of the smaller details so vital for successful treatment, but in a large number of cases they had been able to educate them to this appreciation. Another factor was that they saw the ambulatory patient only once a week at the shortest interval, which was a drawback. On the other hand, there was often difficulty in getting the patient to return at these weekly intervals, because after a few visits he was so improved that he did not feel or understand the necessity of returning as often as requested. Medication presented another hardship, in that they were not able at present to obtain a standardized preparation of digitalis from the dispensary, nor did they receive the same preparation throughout the year. Again, they had no method for the patient to measure accurately his dose of digitalis. While these factors tended to diminish the accuracy of any study of these cases, it must be borne in mind that this was also the condition that existed when the cardiac was under treatment by the average general practitioner. They felt, therefore, that the study of a group of patients under this type of treatment allowed them to make deductions, or possibly elaborate principles which might be of value. The routine followed at the Bellevue Cardiac Clinic was as follows: After the patient's history, physical examination, and diagnosis had been completed by men assigned to this work, the patient was referred to the speaker for treatment. His first interest was the patient's functional capacity, as classified by the Association of Cardiac Clinics. From this, the other data on the chart, and personal observation, he determined whether or not the patient required digitalis. If this was needed, it was prescribed, and the patient instructed as to measuring, symptoms of toxicity, and so forth, and also given directions in regard to rest, diet, hygiene, etc. The patient was requested to return weekly at first and then at longer intervals, depending on his condition. At each visit to the clinic the patient was put through a definite routine; his weight, general condition, the presence of edema, dyspnea, and cyanosis, the heart rate, and regularity, pulse deficit, and blood pressure were all observed and charted, as well as any change in his functional capacity. It was upon these observations that the effectiveness of the medication was judged. The next step was the determination for each individual case of the dose necessary to produce a digitalis equilibrium, namely, the minimum dose that would keep the patient digitalized and compensated under the existing conditions of work. In no case requiring digitalis did they allow an interval between visits of more than four weeks; in nondigitalized cases they allowed up to three months. The patient was thoroughly instructed to recognize the first symptoms of decompensation or of digitalis poisoning and at the appearance of any of these he was instructed to return to the clinic. A check was kept on the patient's attendance, and if he failed to attend he was notified by postal, and then, if not heard from, by a personal call by the Social Service. The report presented was based on the first 250 cases at the clinic, the observation ranging from three to twelve months. The majority of these cases were well advanced in years, though the same conditions might obtain in a group in which the average age was younger. Of this total of 250 cases only 46.5 per cent. required digitalis continuously, while the remaining 53.5 per cent. had never received any digitalis or in some cases only a small initial treatment until occupational or other readjustments could take place. As an index of improvement the lessening or disappearance of dyspnea and pulse deficit were the most important signs, with the amelioration of edema, cyano-

sis, and lung signs next in importance. In the cases classified as improved all these symptoms had disappeared. It was found that as age advanced there was an increasing percentage of cases requiring digitalis. The most prevalent type of disease with which they had to deal was the double mitral, namely, mitral stenosis and mitral regurgitation. The etiological factor in most of these cases was one of the rheumatic triad. This class of disease formed 28 per cent. of all the cases in the non-digitalized series, 45 per cent. in the digitalized with improvement, and 54 per cent. in the unimproved series. However, they did not feel that this had any bearing on the digitalis effect. Of the unimproved cases, 73 per cent. had fibrillations. These cases were returned to the hospital and 57 per cent. of them had died. In the non-digitalized series, 95 per cent. of the patients were at work; this was in reality 109 per cent., as the 5 per cent. not working were idle for other reasons than physical disability. In the digitalis with improvement series, 85 per cent. were working. In the non-improved series, only 18 per cent. worked, all doing light work. These cases were further classified as to those doing heavy, moderate, and light work. In ordering digitalis for the patient they did not allow him to use a dropper, but insisted upon his dropping from the bottle supplied. The lips of these bottles were fairly uniform and delivered about three drops to the minim. They started with 30 drops three times a day and varied this dose later as the requirements arose. When full digitalization occurred they began to decrease the dosage until the patient again showed the early signs of decompensation, when the dose was again increased. After several attempts with this procedure they were finally able to determine the minimum dose which would keep him digitalized, or in "digitalis equilibrium." With this dose the patient could be kept under medication indefinitely. They found that 71 per cent. of the patients received from 20 to 30 minims a day; the remaining 29 per cent. were about equally divided above and below this dosage. They had not worked out any relationship between the amount of digitalis and the body weight, nor could they find any relationship between the dosage and the type of work. Apparently the etiological factor and the anatomical diagnosis did not affect the digitalis dosage. They had further subdivided the digitalized cases with improvement into regular and fibrillation types, but were again unable to find any difference. The upper limit of digitalis dosage was 45 minims a day for an ambulatory cardiac; if no beginning improvement followed this dosage after a week's trial they felt that such a patient was a hospital case. Overdigitalization was an infrequent event at the clinic, there having been but seven such occurrences in the past twelve months. They were frequently confronted with the symptom of nausea alone, even after the first dose of digitalis, but did not feel that this was a reliable symptom of overdigitalization without other evidences. They had found that if the patient took a glass of water after each dose of digitalis this symptom did not occur. He was not in agreement with the old idea that digitalis should be stopped at regular intervals. They had had a considerable number of patients taking the dosage determined for them over periods of ten, twelve, and thirteen months without showing any signs of overdigitalization. Seven patients who received digitalis and were not benefited proved to be cases of terminal fibrillation. The value of the cardiac clinic was shown by the fact that they had been able to keep the majority of their cases compensated, at their work, and out of the hospital.

A Consideration of Occupation in Its Relation to the Adult Chronic Cardiac.—Dr. JOHN WYCKOFF read this paper, in which he said that to patients attending a public clinic the ability or inability to gain a livelihood was of paramount interest. A physician in the clinic wondered if changing a certain patient's occupation to a lighter one might not improve his condition. Again he might wonder whether a patient who seemed perfectly able to do the hardest work might not be injuring his cardiac musculature and gradually impairing his reserve by so doing. And, then, in some patient inclined to make his cardiac affection an excuse for doing little or no work, he might wonder if some occupation which called for exercise might not be of material aid

in building up the reserve which they all wished to get in their cardiacs. Questions of this nature they had been endeavoring to answer for the past eighteen months. They had noted changes in occupation and the results obtained by such changes, and while the number of cases studied was too small to be of great value, he believed it wise to take stock in this preliminary study (1) for the purpose of seeing whether even at this early date some helpful points might not be derived from such a study, and (2) to see whether this recapitulation would point out avenues of inquiry neglected thus far, which might be inaugurated without further delay. For the study they had used patients of Classes 1, 2, and 3 of the classification of the Association of Cardiac Clinics, who had been under observation for at least six months and who had attended the clinic with sufficient regularity for the observers to have a proper appreciation of their condition. The study included 152 cases that met the above requirements. The occupations were divided into three classes, depending upon the amount of effort called for, namely, heavy work, moderate work, light work. In considering the ability of the patients to carry on their occupations they had classified them as: (1) Those able to carry on normally. (2) Those able to carry on well enough to hold their positions, but who had difficulty in doing their work. (3) Those unable to carry on. Of the 152 cases, 105, or 69 per cent., were men and 47, or 31 per cent., were women. The greatest number of men were in the fourth and sixth decades, while the greatest number of women were in the fourth and fifth decades. After the fifth decade the number of women fell to nearly none, and this did not happen until ten years later in the case of men. Of the whole group, 35.5 per cent. were doing heavy work, 35 per cent. were doing moderate work, and 29.5 per cent. were doing light work. Of the group doing heavy work, 21 per cent. were able to carry on well; of the group doing moderate work, 42 per cent. were able to carry on well, and of the group doing light work, 74 per cent. were able to carry on well. It would seem that of patients having organic heart disease, 75 per cent. are able to do light work. Of the 152 patients, 38, or 25 per cent., were in Class 1 of the classification of the Association of Cardiac Clinics; 85, or 60 per cent., were in Class 2, and 29, or 19 per cent., were in Class 3. Of Class 1 patients, 94.4 per cent. were able to do heavy work, and there were none who could not do heavy work at all. Of the Class 2 patients, 16.6 per cent. were able to do heavy work; 16.6 per cent. were able to do heavy work with difficulty, and 66 per cent. were unable to do heavy work. Of the Class 3 patients, only 10 per cent. were able to do heavy work, 27 per cent. did heavy work with difficulty, and 73 per cent. were unable to do heavy work. After a further analysis of statistical data, Dr. Wyckoff concluded as follows: (1) Women with organic heart disease did proportionately heavier work than did men. This, he believed, was not because of their greater physical ability, but because of the greater difficulty women over the age of thirty had in changing or modifying their vocations. (2) They believed that patients with organic heart disease should, if they did any work, do light work for the following reasons: (a) Patients who had had one or more attacks of heart failure had little ability to carry on heavy work even for six months, but they had nearly normal ability to do light work for that period of time. (b) Heart failure manifested by inability to carry on work occurred more in patients doing heavy work and moderate work than in patients doing light work. (c) Since patients who were unable to do heavy work were frequently able to do light work, one might infer that patients doing light work remained self-supporting over a longer period of time. (d) Inasmuch as it was easier to procure a change of employment for a patient who was in good physical condition than for one who was partly incapacitated, patients who were able to carry on with heavy or moderate work even well should have the nature of their work lightened at the earliest possible moment and should not wait until signs of distress manifested themselves. (3) Patients with auricular fibrillation must be kept digitalized, otherwise but few of them could work. (4) Patients with auricular fibrillation who when digitalized were unable to do light work had a poor prognosis.

Dr. L. T. LE WARD said this symposium had been of

a great deal of interest to him, since he had at one time been interested in hearts from the pathological standpoint and later from the standpoint of the roentgenologist. He then illustrated by means of lantern slides his conception of estimating the size of a heart and showing a great deal of the pathology that occurred. One of the most important points in connection with the estimation of the size of the heart was the question of the influence of respiration on the size and position of the heart. If one saw the same individual in the two extreme phases of inspiration and expiration it would be found that there was much the same difference as between the two types of habitus. If there was such a difference in the size of the heart in the two phases of respiration, how was one going to compare the results? To his mind one could control these two factors by two electrical devices. One of these devices recorded the time of exposure of the cardiac cycle. Professor Bardeen had done much to stimulate careful measurements of the heart and had devised a method of recording what he thought were the systolic and diastolic phases which had been substantiated by Professor Eyster. A spark was made to pass from the x-ray machine and was recorded on the electrocardiogram when the exposure was made. The first record was made at the beginning of the respiratory curve, and there was a record at the time of inspiration and of expiration. The method of estimating the size of the heart described by Dr. Hirsch was new and very elaborate and probably as accurate as any other method. It furnished another method of ascertaining the size of the heart, provided one had control of the phases of respiration and of heart action. Dr. Le Wald stated that he believed the usual measurements, transverse diameter, etc., were relatively accurate, and as accurate as Bardeen's method. There was no absolutely accurate method that could be entirely relied upon at the present time. One could approach this by taking a series of exposures at a two meter distance and then getting the average. The average of six or seven exposures would give a fairly definite and accurate measurement. Among the slides which Dr. Le Wald showed was one which he said he regarded as the hypoplastic heart. We should pay more attention to small hearts than we ordinarily did. Another slide showed one of the largest hearts Dr. Le Wald had ever seen. Then passing on to the point brought out in the paper that a cardiac lesion was no contraindication to a certain amount of effort, it was necessary to study these hearts fluoroscopically, because, as shown by the slides, a heart might look very much hypertrophied from the anterior viewpoint, while from the side view one could see that it resolved itself into two shadows—a heart shadow and an enormously dilated aorta. Another slide showed a calcified pericardium. This was observed in the course of an examination of a woman with carcinoma of the pylorus. He had given it as his opinion that this condition was not sufficient reason why this woman should be denied any possible benefit from a radical operation, and she went through the operation successfully.

Dr. HAROLD E. B. PARDEE said he was much interested in the roentgenographic work on the heart, but did not feel competent to criticize it. He did not think that at present any information from the x-ray was of much help, but he thought this new lead might turn out to be of value. The digitalis paper had interested him particularly because he was doing work of that type at the night cardiac clinic of the New York Hospital and had recently published data on what they had found. He had found the same variation in the figures of daily average dosage as Dr. Pellini. He had found the amounts of digitalis very much the same, ranging from 15 to 30 minims a day over very long periods. It was a very important point in treating ambulatory cases that one could not be guided by the minims but by the results. One must keep giving enough digitalis to get the effect on the heart. An important point was to avoid poisoning. One could not give digitalis by measure, but had to watch the symptoms, the heart, and the circulation, and must give enough to produce results without knowing beforehand just how much would be needed. It was a great help to know approximately how much one was giving. They had adopted a measure of giving out a bottle containing the mixture and then telling the patient to bring back the bottle to see how much he had taken.

In private practice he gave tablets and then had the patient tell just how many tablets were left. Dr. Pellini mentioned pulse deficit as one of the signs by which one could judge improvement. It seemed to him that the relation of heart rate to pulse rate afforded a better means of judging. The pulse deficit was the result of heart rate and pulse rate, the result of subtracting the one from the other. The objection to the use of the pulse deficit was that in digitalis poisoning extrasystoles were produced and the pulse deficit included these extrasystoles. The thing we wanted to know was the relation of heart rate to pulse rate and why it was such. Another point that might be mentioned was sudden death from digitalis. While this did not happen today as frequently as it did in the past, Dr. Pardee said he had seen patients given too large doses of digitalis and they had shown extrasystoles, and the giving of digitalis had been continued, the result being a sudden death. The effect of auricular fibrillation on the patient's ability to perform work was very clearly brought out in the paper of Dr. Wyckoff. It did not have much effect, in Dr. Pardee's opinion, and Dr. Wyckoff had showed this. Professor Eyster had published some work on the effect of irregular rate of the heart on blood pressure, and had shown that with experimental auricular fibrillation the blood pressure fell. With a slight irregularity due to extrasystoles—an irregularity comparable to the clinical auricular fibrillation properly slowed by digitalis—there was no fall in the blood pressure.

Dr. MARCUS A. ROTHSCHILD congratulated the physicians in charge of the clinic at Bellevue for their efficiency in research and for the careful manner in which their preliminary observations were presented. He felt that the section should appreciate the value of receiving the results of such preliminary observations. The work of Drs. Hirsch and Shapiro on status was extremely interesting and when further developed should prove of value. However, he agreed with Dr. Le Wald that the x-ray photographs of the size of the heart had not proven of great value, but fluoroscopy, especially in reference to the contour, was of great service. The observations of Dr. Pellini were in accord with the observations made at the cardiac clinic at Mt. Sinai. The relationship of occupation to the adult cardiac was the problem which he had been especially asked to discuss. He felt he knew less about this phase of the subject because of his intense interest in it. He regretted that Dr. Wyckoff had not told the section some of the difficulties in placing these people in occupations. The social service worker had investigated 140 cases attending the clinic, 72 being women engaged in household work—occupations which could not be changed. As Dr. Wyckoff has pointed out, these women were doing heavy work. He wondered if this had anything to do with the fact that in Dr. Wyckoff's chart no woman over 50 was engaged even in moderate work, presumably because they had all died before reaching that age. The 68 remaining cases attending the clinic were males, only one of whom was engaged in heavy work. In endeavors to change the occupation of these cardiacs they had met with very little success, the patients claiming that the change in occupation would mean a decrease in income, which they could not afford. From the standpoint of the employer, while they had had a small amount of cooperation, the results had been disappointing. Many employers said they would rather give a person who was not able-bodied and capable of working full time, a thousand dollars than employ him, because such a person was disorganizing to the industry. It must be remembered that the ability of a cardiac patient to carry on in any occupation for one year was no absolute test of the fact that the occupation was not harmful. He had seen a case of aortic insufficiency do front-line trench duty for approximately one year before manifesting all the symptoms of cardiac failure. It appeared that a more comprehensive plan would have to be developed in relationship to the adult cardiac. It was possible that certain groups of cardiacs might have to be placed in special organizations or factories, as had been done with patients with tuberculosis. At present there was a big gap in the proper handling of all cardiac cases. We had the hospitals for the handling of the acute cases and a limited number of convalescent homes for the aftercare. It appeared essential that there be developed

special hospitals whose function should be intermediate between the acute hospital and the convalescent home. The papers of the evening showed the value of accurate work and especially the value of an accurate follow-up system in solving some of the questions in regard to the care of the adult cardiacs.

Dr. ALEXANDER LAMBERT said one thing he thought the study in the clinics had shown was the fact that one must learn to gauge the work a cardiac patient could perform by making some estimate of the functional capacity of the heart. One could divide the work into heavy, moderate, and light, and then there would be an indefinite something which enabled one to tell what the individual cardiac patient could do. As to murmurs, it did not make so much difference whether there was a loud murmur or a light murmur; the important thing was the power of the heart to dilate and recover and to keep the body supplied with blood and the blood with oxygen in an even, straight line—in a well balanced way—when at work and at rest. The question of function was an element in the study of the heart in which the dispensary offered advantages over the hospital. MacKenzie was perfectly right when he said there was more to be learned about the heart in the dispensary than in the hospital. The hospital was valuable in teaching what could be done in the reconstruction of a broken down heart, and the practical value of this or that remedy or method of treatment. The hospital had taught the value of treatment in syphilitic hearts and had taught the hopelessness of some comparatively slight injuries to the heart, but in the dispensary one gauged the amount of work a heart could do and this was most valuable. While Dr. Hirsch was reading his paper it had been interesting to see where it would lead. He thought Dr. Hirsch had reached the place where he said: "These are the facts. What are we going to do with them?" What conclusions are we to draw from the lines and curves we have found? What relation do they have to disease as we find it and to the morbidity of cardiac disease? What do they show of the power of the heart to accommodate itself to exertion?

Dr. SAMUEL A. BROWN emphasized the fact that we were treating in the hospitals many cardiac cases that could be treated just as well or better in the dispensary. This was an important matter from the standpoint of hospital administration, and should lead to a weeding out of these cases. A second point to be emphasized was that the sooner we came to forget valvular lesions and study muscular efficiency and functional ability of the heart the better would be the treatment and the better the prognosis in these cases. In years gone by every cardiac patient received digitalis just because he was a cardiac case, but this had been changed by the study of the action of the normal heart musculature and the effects of fatigue and exhaustion and by a careful estimation of the functional capacity of the heart. More attention to these factors would result in fewer disappointments in the treatment of these cases and more intelligent prognosis.

Dr. HIRSCH, in closing, said that the point he had desired to make had apparently not been fully appreciated. He was pleading for a consideration of the thoracic viscera from the viewpoint of their relationship to the habitus of the individual. The first question, therefore, in the study of the heart was did it conform morphologically to that habitus? If it did not, then in what way and why did it not correspond? Considered from this viewpoint, such conditions as "drop heart," "hypoplasia of the heart," and "horizontal heart" were but normal variations. According to such a classification, the case of hypoplasia shown by Dr. Le Wald would fall in the classification of the heart of the asthenic. Before the classification of the gastrointestinal tract according to habitus it was thought that a stomach below the interspinous line was posited. We now knew that such a stomach was perfectly normal for a particular habitus. The so-called standard measurements had never been enthusiastically adopted clinically because they were of no practical value on account of their apparent variability. Thus an individual fifty-eight inches high might, according to Groedel's tables, have a transverse measurement practically the same as one seventy inches high. According to Clayton and Merrill's tables, a man weighing 110 pounds might have a transverse diameter of 10.7, while one weighing 175

pounds might have a total transverse diameter of 11.0. But the standard heart measurements, taken in connection with the habitus, appeared to be more practical. The figures were analyzed according to weight, angle of inclination, and size of pulmonic fields (for these factors were the expression of habitus). Yet, even when considered from this viewpoint, the measurements did not give any certain indication of beginning changes in the heart walls or in the capacity of the heart chambers. It was for this reason that the study of the curves for the determination of such early morphological changes was taken up.

Dr. WYCKOFF, in closing, said that Dr. Rothschild had wondered whether all the women in this series over 50 were dead. He had thought of that point and supposed none of them had survived. With reference to the question of placing these patients in suitable occupations, they had had a tremendous amount of difficulty. He had not gone into this phase of the question in the paper because in the twenty minutes allotted to the reading of the paper there were many points that could not be touched upon. The data in the chart did not include everything. In the Class 2 cases in the clinic they were unable to place possibly 60 per cent. of the cases. During the past year they had had a large clinic and with the shortage of labor it was easily possible to place many patients, but during the coming year they were going to have a very difficult time. One reason they had been able to place so many of their patients was because of the great efficiency of their social service worker, who was very persistent. Dr. Wyckoff cited specific instances illustrating the difficulties encountered in placing patients in suitable employment.

Dr. PELLINI, in closing, said he was interested in hearing Dr. Pardee say that he had the same figures for dosage and that he also found that digitalis could be administered over long periods without producing symptoms of overdigitalization. With reference to the disappearance of the pulse deficit as a sign of improvement, due consideration had been given to extrasystoles. The pulse deficit was only one of the factors considered in determining improvement, but it gave a good deal of information.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

PRACTICAL PSYCHOLOGY AND PSYCHIATRY. By C. B. BURR, M.D. 269 pages with illustrations. Published by F. A. Davis Company, Philadelphia.

VITAMINES. By BENJAMIN HARROW, Ph.D. 219 pages. Published by E. P. Dutton & Company, New York.

AMERICAN RED CROSS WORK AMONG THE FRENCH PEOPLE. By FISHER AMES, JR. 178 pages with illustrations. Published by the Macmillan Company, New York.

DER GYNÄKOLOGISCHE OPERATIONSKURSUS. Von Prof. Dr. WILHELM LIEFMANN. 488 pages, with illustrations. Verlag von August Hirschwald, Berlin.

THE ENDOCRINES. By SAMUEL WYLLIS BANDLER, M.D. 486 pages. Published by W. B. Saunders Company, Philadelphia.

MYELOCYTIC VARIATIONS IN LEUKEMIC BLOOD DURING TREATMENT.

BY EDWIN SCHISLER, M.D.,
PHYSICIAN TO ST. LOUIS CITY HOSPITAL,
AND
E. EUGENE BROWN, A.M., M.D.,
ST. LOUIS, MO.

IN the classification of leukemia, two forms are recognized: the myelocytic or myeloid and the lymphoid. Numerous cases not fitting into either group are spoken of as "atypical" or "transitional" forms. Numerous such cases have been reported as stomatitis or hemophilia and the myeloblastic nature of the disease was discovered only at autopsy.

The nature of the disease is unknown—Banti, Warthen, and others regard the disease as related to sarcoma and myeloma. The acute cases resemble clinically an infectious process. Much blood culture work has been done during the past few years but no organism has yet been isolated.

Bennet¹ in 1845 recorded a case of suppurative of the blood with enlargement of the spleen and liver which he called leucocythemia. He was followed one month later by Virchow who described a like case calling it leukemia. In 1870 Neumann demonstrated the part played by the bone marrow. Myelogenous leukemia was first described in 1896 by Von der Weg.² Billings and Capps³ presented nine cases from the literature of 1903. Wolfer⁴ in 1910 brought the total up to twenty. Since then the report of cases has become more rapid especially since the beginning of more successful therapy.

The treatment has been surgical, x-ray, benzol, and radium. The surgical treatment has always been "a tragic story" with a mortality of 85 to 93 per cent. Splenectomy by Warren⁵ in forty-three cases gave five recoveries in various types of leukemia. Griffin⁶ of the Mayo clinic reported twenty cases of splenectomy for myeloid leukemia, in which nine were fatal within one year. In the others the disease followed its usual course. The age did not affect the mortality. The improvement following operation was variable, usually the patient was more comfortable. Griffin⁶ suggested that this may have been psychic and says operation is only justified in chronic cases. The blood picture was unchanged. There seemed to be a compensatory reaction and an abnormal functional hyperplasia in the long bones.

X-ray treatment was taken up in the treatment of leukemia with its use in carcinomata. The spleen and long bones, *i. e.* the tissues from which the abnormal blood cells were produced, were the

points of application. The success of x-ray in this respect has been variable. Some observers found temporary falls in the white blood count after x-ray applications, but in general little effect upon the ultimate course of the disease. Others found reduction in the size of the spleen after its use, but after some checking of the process with temporary relief of symptoms, the cases terminated fatally. An occasional case has given very remarkable results, the patient living and well for two or three years with occasional doses of x-ray after the initial course.

Benzol has been used as a treatment for the leukemias since Koranyi⁷ in 1912. His clinical use of benzol was prompted by an accidental run of three cases at the Johns Hopkins Hospital in 1909. Three young girls working in crude benzol presented evidences of a grave aplastic anemia and a striking leucopenia. Snelling⁸ demonstrated experimentally the powerful leukotoxic action of benzol. Koranyi⁷ used the drug clinically with no ill effects and some success. Kiralyfi⁹ reported seven cases under successful benzol treatment, *i. e.* clinical symptoms disappeared and the blood picture returned to normal in from three weeks to five months. Stien¹⁰ reported one case after six weeks and another after two months. Billings¹¹ gave five cases suggesting further use of the drug.

Following this, many workers adopted benzol therapy. Klein¹² reported twenty-two cases with fair results suggesting, as Rösler¹³ did, that the time of observation should be much lengthened for definite reliable conclusions. Watchel in 1913 produced albuminuria on the third day in one, but treated two other cases successfully, as to decreasing the leucocyte count but pointed out that the myelocytes were still present.

Koranyi in 1913, one year after his first paper, reported two cases failing, in one the drug was not tolerated, in the other benzol had no effect, nor did the x-ray or thorium. Quadroni and Buzzano¹⁴ reported little benefit in four cases. Klemperer and Hirschfeld¹⁵ first determined the toxicity and harmful effects of the drug in 1913. Jespersen's¹⁶ case showed an immediate fall to normal in white blood count, but without treatment recurrence was very rapid, the patient dying twenty-two days later. Neumann¹⁷ had a case thirty-six days on benzol and cleared up all symptoms but upon suspension of treatment a very rapid remission occurred with diarrhea, epistaxis, stomatitis, rhinitis, and fever. He questioned the part benzol had in bringing on such an acute exacerbation. Jenkins and Meyer¹⁸ brought out the lack of uniformity on the action of benzol and again suggested long and careful observation in its use before definite trustworthy conclu-

sions were drawn. In certain of their cases it failed to reduce the count to normal, in some the size of the spleen was unchanged, in others the white blood count underwent very sudden changes, both increase and decrease. Muhlman¹⁰ at autopsy after benzol found liver necrosis in the lymphatic type. Neumann¹¹ gives the same findings in the myeloid form. Pappenheim¹² produced this same liver necrosis experimentally in rabbits and clinically reported gastro-intestinal irritation and renal injury from the use of benzol. The dosage heretofore was suggested by Koranyi¹ beginning with 0.5 gm. three times a day and gradually increasing until toxic signs appeared.

The x-ray alone has been found ineffectual as was stated above but when benzol and the x-ray were used conjointly, the action of benzol was seemingly augmented. Smith⁷ in 1914 presented a case of myeloid type treated on benzol alone. He reported flare-ups only when the patient was home on visits and suggested much rest in bed necessary for successful therapy. He found that the myelocytes persisted in the blood picture although the count was normal and the spleen was reduced to normal size. Sappinton and Pearson¹³ found that, with combined x-ray and benzol therapy in myeloid leukemia, the white blood count remained low with a slight relative mononuclear increase, the spleen stationary and the patient well during two years' observation. Smith⁷ in 1915 concluded from his cases that benzol alone is a symptomatic treatment and is inhibitory to the production of white blood cells. During the last few years the combined treatment of x-ray and benzol has been used with variable success, certain cases respond to one or the other, an occasional acute form to neither. In one case of a farmer, the chronic form was treated by the combined method until the spleen was reduced and the count about the usual 20,000. The symptoms disappeared and the patient was subjectively well and working. With a short period of treatment every six or twelve months, the patient's life was prolonged for six years. Yacquez and Yacod¹⁴ reported in 1918 three cases of myeloid leukemia on doses of forty to one hundred drops of benzol a day, the first twelve days of each month, running from two to six months with beneficial results, after the x-ray had failed to affect either of the cases. In contradistinction Griffin⁶ published a series of thirty cases treated with a dosage of fifty to one hundred milligrams, exposing the spleen once a week, twenty-four to thirty-six hours total, with beneficial results. His average results were a decrease of leucocytes, an absolute and relative fall of myelocytes, an absolute fall in polymorphonuclears, the percentage remaining constant, and a fall in absolute count of small lymphocytes. Suffice it to say since cases vary themselves, that the x-ray and benzol or their various combinations, whichever proves effective, is the desired treatment. The treatment should be compromised and fitted to the individual case.

Renon, Degrais, and Tournemelle¹⁵ in 1914 reported twelve cases, in eight of which the x-ray had failed, and which were benefited by radium. Pinch¹⁶ in 1915 noted excellent results in one case. Von Noorden and Falta¹⁷ in 1911 found no favorable results. Thorium and mesothorium have been found to have similar effects as radium. Here too the re-

ports are variable. Certain cases showed remissions, with Falta, Kriser and Zehner.¹⁸ Kaufmann¹⁹ reported reduction in the size of the spleen and subsidence of symptoms, the blood picture approaching normal over a course of one and a half years. Ordway and Gerhan²⁰ reported in 1920 results in one case where all myelocytes disappeared from the blood after three doses of radium, after benzol had given toxic effects and x-ray had given no improvement. Three months later a fatal acute exacerbation occurred. Radium, while active in reducing the white count, is uncertain in dosage, not well controlled and difficult to procure.

In this case an attempt was made to determine the extent and nature of the action of benzol and the x-ray, separately and combined, upon the blood picture in a rather severe case of chronic myeloid leukemia. The changes were followed in not only the red and white cells but also in the types of white cells and moreover in the various types of myelocytes. The relative changes and the absolute changes with the complete differential estimates are shown in Tables I and II and the curves plotted (Charts I, II and III).

CASE.—C. P., white male, 45 years old, single. Family history negative except mother died with dropsy. Past history: Usual childhood diseases, no sequelae. Patient was a laborer doing heavy work, was strong and healthy (except recurrent gonorrheal infection in youth), until September, 1917, when he was ill four weeks with typhoid fever. In July, 1918, he began to notice palpitation of the heart, occasional swelling of the feet and ankles, and shortness of breath especially after climbing stairs. At about the same time he began gradually to develop a slight loss of weight and strength, loss of sexual power and priapism, giddy sensations, tinnitus, and vertigo. In January, 1919, his abdomen began to enlarge and with this came constipation, a feeling of pressure after eating, shortness of breath, and increased frequency of urination. By April, 1919, the symptoms had progressively become worse and the hair had begun to fall until, on July 15, 1919, alopecia was complete. The patient was now quite weak, complaining of very poor appetite, unsteadiness in gait with dizziness and tinnitus; shortness of breath, severe constipation, slight fever, bloody stools, and epistaxis. Beginning July 19, 1919, the patient says he was treated for three weeks without improvement for liver trouble. He was admitted to City Hospital August 22, 1919. Examination showed a white male poorly nourished, of moderate development. Pale and weak in appearance, temperature 99°, pulse 80, respiration 20. The skin was dry, cool, with purpuric blotches over forearm, face, scalp, and back. The glands were generally enlarged, firm, discrete, and not

tender. There was complete alopecia. A right nasal pterygium extended just over the corneal edge, the sclera was pale. The middle left turbinate was hypertrophic, causing partial obstruction. The teeth were fair, but the gums bled easily, the mucous membrane being quite pale. Impacted cerumen was found in the right ear, tympanic membranes were pale. Neck showed no abnormal pulsations, no abnormal findings in lungs except a slight edema at bases. Temporals tortuous and thickened, radials slightly thickened.

in flanks, fluid wave elicited. Tenderness over spleen but no crepitus, pulsations, or murmur. Rectal examination showed the sphincter rather spastic, slight hemorrhoids, prostate quite tender, enlarged, thickened laterally, rather firm in consistency. The gait showed a broad base, Romberg's symptom positive, superficial and deep reflexes normal.

Laboratory: Urine showed a faint trace of albumin and a few pus cells on the first two days in hospital, none afterwards. Admission stool showed occult blood, no microscopic blood. Blood specimens taken once a week for three weeks were persistently negative as to Wassermann, Widal, tuberculous complement fixation, and blood culture. The blood showed hemoglobin 50 per cent red cells 1,500,000, white cells 960,000, polymorphus 32 per cent, small lymphocytes 11 per cent, myelocytes 57 per cent, of which 50 per cent were neutrophilic, 4 per cent eosinophilic, and 3 per cent basophilic.

The patient was immediately put upon benzol and x-ray therapy combined, later on September 11 upon x-ray alone, and October 15 on benzol alone, as too great a reduction of white count was undesirable. The patient left the hospital November 4 against our advice and was requested to report every week for observation, but failed to report until January 10, 1920. He then re-entered hospital complaining of constipation, sore throat, and small amount of urine. Physical examination revealed briefly the following: Scalp was covered with fine thin brown hair with several scattered denuded or crusted areas and pigmented scars, all about 1 cm. in diameter. Left pupil a trifle larger than right, both regular and reacting promptly to light and accommodation. Membrane of the right ear congested along the long handle of the malleus, little retraction right or left, color not abnormal, hearing slightly impaired. Glands showed no enlargement. Lungs were clear, outline of cardiac dullness, 10.5 cm. to the left in the fifth intercostal space, no accentuation, a soft systolic murmur at the third space to the left. Abdomen was tympanitic, distended, and enlarged; spleen 6 cm. to left of midline and 6 cm. below the costal margin; liver palpable, 3 to 4 cm. below the costal margin and slightly tender. Reflexes were negative. Left testicle slightly larger than the right, no tenderness, otherwise negative. Sexual power had returned during the previous treatment but had waned during the past month; the patient had married since previous discharge. The patient was given combined

Cardiac dullness extended 11 cm. from the midsternum in the fifth intercostal space. Systolic blowing murmur over base not transmitted, aortic second sound roughened and impure, some accentuation of pulmonic second. Abdomen, pot-bellied, distended, rising 8 cm. above the level of the costal margin. Panniculus medium, liver extended from the fourth intercostal space to 3 cm. below the costal margin, tender to palpation. Spleen very much enlarged, extending 4 cm. to the right of the median line and downward to the level of the anterior superior spine of the ilium. Shifting dullness

x-ray and benzol, and improved readily, the white count being reduced from 137,000 to 40,000, when, again being free from symptoms, he insisted on leaving the hospital and the city February 14, 1920.

White counts were made by the same observer and counting apparatus, usually every second day, red counts and hemoglobin once a week. Differentials were made about every fourth day; in every count at least two hundred cells were counted and the treatment varied as shown in Tables I and II. The spleen was carefully outlined each week, the changes being as shown in the accompanying illustration. We wish to thank Dr. L. R. Sante, roentgenologist who furnished Table III, for his kind and helpful interest and cooperation.

From the accompanying charts it would seem that the x-rays and benzol together produced a rapid permanent fall in the white count while the x-rays alone produced an immediate rapid fall with a subsequent rise in the first instance to the same count as before exposure and in the second trial a decrease with a subsequent rise to about one-third the count preceding exposure. Next an attempt was made to give two x-ray exposures, the second timed just before this subsequent rise, with the result of a more or less continuous fall in the count. Since a third x-ray exposure would be dangerous, the subsequent rise was counteracted by resumption of benzol, which seemed to hold the count steady. Arsenic and

iron were given during the first week with an increase of hemoglobin and some increase of red cells. The color index returned to normal as the blood constituents approached normal limits. The red count and hemoglobin were not markedly affected by either benzol or x-ray but increased steadily as the patient's condition improved. The differential count showed a more or less continuous relative increase of polymorphonuclear leucocytes with a corresponding fall of myelocytes. The relative lymphocytic count after a slight initial increase remained more or less stationary.

The x-rays seemed to destroy polymorphonuclear leucocytes or to slow up their production, but relatively had no such effect upon the red cells or their production. After x-ray exposures the blood smear showed numerous disintegrating white cells. Since the spleen was exposed they were seemingly destroyed within the spleen, hence producing a relative decrease in the circulating blood. Myelocytes showed a tendency to give way to an increase of large mononuclear cells whose nuclei in turn became lobulated, elongated, and horseshoe-shaped with a relative increase in polymorphonuclears. After the x-rays the myelocytes were still persistent in the

blood picture and in the various neutrophilic, basophilic, and eosinophilic forms, the eosinophilic persisting longer than the basophilic. Polymorphic eosinophiles persisted until late in the course, until only neutrophilic myelocytes were present. After the first two weeks eosinophiles were found only occasionally. The x-rays in every trial produced a decrease in the absolute number of small lymphocytes but had no constant effect upon the relative count. Myelocytes were not so affected, relatively they were decreased by the x-ray with no constant effect upon the absolute. Benzol, on the other hand, caused a steady fall in the absolute count but did not affect the relative myelocytic count. Polymorphonuclears were destroyed constantly and rapidly by each dose of the x-rays. The absolute count was affected more markedly than the relative. Benzol gave a slighter

x-rays. The x-rays had less effect on reducing the myelocytes than the lymphocytes and leucocytes.

Summary.—1. Benzol does not affect the negative Wassermann reaction.

2. Repeated blood culture showed no growth.

3. Combined benzol and x-ray treatment adapted to a particular case and constantly checked by white cell and differential blood counts, gave at least a temporary and complete relief from symptoms and a satisfactory decrease in abnormal blood cells, the differential count approaching normal limits.

4. Periodic treatment continued at three to six month intervals can keep the patient free from symptoms and definitely prolong life in the chronic form.

GRAND AVENUE AND SIDNEY STREET.

Fatal Cerebrospinal Meningitis from the *Micrococcus Catarrhalis*.—Lemaire and two others report two cases of this affection which were due to the above-mentioned organism. The patients were nurslings. Despite the use of an autovaccine death ensued. The occurrence in such young children of meningitis due to germs of low virulence is pronounced common.—*Le Bulletin Médical*.

absolute decrease of polymorphonuclears than the x-rays and a more constant and rapid increase relatively. Basophilic myelocytes disappeared readily under benzol only to reappear temporarily after each dose of x-rays. As the blood picture approached normal limits, the basophilic myelocytes were reduced under benzol, reappearing when benzol was discontinued and again present following x-ray administration; on resumption of benzol they again disappeared. In variation of the myelocytes, the eosinophilic count conformed generally with the neutrophilic change, but increased or appeared with each administration of the x-ray. Neutrophilic myelocytes showed a gradual steady fall under benzol with a corresponding increase in polymorphonuclear leucocytes relatively. On discontinuing benzol a distinct and marked absolute increase occurred but was controlled with repeated doses of

THE BORDET-GENGOU REACTION IN AORTIC LESIONS.*

By E. GOYNAROFF, M.D.,

GENEVA, SWITZERLAND.

THERE is at present little doubt that a relationship exists between aortitis and syphilis, particularly for the last fourteen years, that is to say since the time that search for the fixation complement in the blood has found its clinical applications. Moricaud (*Contribution à l'étude de la réaction de Wassermann chez les aortiques*, Thesis, Paris, 1914) published a very interesting study on the subject, showing the great importance accorded by this writer to the part played by syphilis in aortitis. He brings forward the results of his researches, preceded by a very complete history of the subject, which I will briefly sum up.

Already in the XVI century, Ambroise Paré suspected the luetic etiology of aortitis, while later, Fernel and some other clinicians likewise considered syphilis as a frequent cause of aortitis. On the other hand, at the beginning of the XIX century, Scarpa denied any relation between syphilis and aneurysm, while on the contrary, Nélaton, Broca and Ricord affirmed that there was. In about 1860, Aitken, of England, found syphilis seventeen times out of a total of twenty-four cases of aneurysm. In 1897, Fournier and Etienne, likewise Laveran and Dujardin-Baumetz very frequently noted this affection in the antecedents of patients with aneurysm. Out of a total of 3728 autopsies, Gron found a history of syphilis in 41 per cent. of subjects with aortic ectasis.

But it is only in reality since 1900 that observers began to pay attention to "syphilitic aortic insufficiency." Deguy, in his thesis, and Huchard, in his treatise on diseases of the heart and aorta, refer to the frequent coexistence of lesions of the aorta and nervous disturbances related to syphilis. At the Société Médicale des Hôpitaux de Paris, in 1901, Babinski went so far as to say that "when in a patient aortic insufficiency is found along with a lymphocytosis in the cerebrospinal fluid and a positive Argyll-Robertson symptom, this is sufficient for affirming the existence of syphilis." This viewpoint has been confirmed by Vaquez, in 1902, and in 1908, by the late Prof. Debove.

From this time, which corresponds with the discovery of the Bordet-Gengou reaction, statistics of cardiac lesions in syphilitics have multiplied and in his thesis published in 1912, Bricout gives a very complete study of the subject and a summary of all the publications that had appeared to that year. Also, in 1912, Ledermann and Delsoulier published large statistics.

Then, in 1914, came Moricaud's monograph. His researches were carried out on thirty-four cases with the hereditary and personal antecedents carefully recorded. A minute examination of the nervous system was also carried out in each case, as well as radiographic studies. There were ten cases of aortic aneurysm, seven of whom present a positive fixation reaction of the blood, the remaining three being negative. Of four cases of aortic insufficiency, two gave a positive reaction, and two a

negative one. There were six cases of aortic stenosis, three with a positive and three with a negative Wassermann. Three cases of aortitis, one of which with a positive and two with a negative Wassermann. Finally, under the heading of multiple lesions, Moricaud comprises eight cases, four having a positive and four a negative Wassermann. This observer remarks that syphilis was unknown to the patient in eleven cases out of seventeen in which Wassermann was positive and that in the fourteen cases of negative Wassermann syphilis could be suspected in two cases of aortic aneurysm, in one of aortic insufficiency and one of aortitis.

Moricaud concludes that "the part played by syphilis in the production of lesions of the aorta is becoming more and more evident," and in his way of thinking the Bordet-Gengou reaction is of the greatest interest, since it permits "in a large number of cases the detection of a latent syphilis." However, he adds that "when a Wassermann is negative, it should not be concluded that syphilis is absent in the antecedents of aortic patients, because in many cases unquestionable syphilitic aortic lesions may not give a positive reaction."

I am unaware that any other paper on this subject has been published since 1914. Prof. Bard being very interested in this subject has had the Bordet-Gengou reaction made in the majority of cases of aortic lesions under treatment in his service and he requested me to collect and publish the results so far obtained.

The cases reported in brief below were carefully studied clinically and an attempt has been made to ascertain if in all cases of aortitis syphilis must necessarily be regarded as the cause even when no clinical sign of the disease existed, and if this be not the case to determine the factors which might explain the positive character of the reaction in a certain number of subjects with aortic lesions. The results of my studies, with a few words on the clinical history of each case, will now be given.

GROUP I.

CASE I. Female, divorced, aet. 63 years, aortitis, aortic and mitral insufficiency, old syphilis. Married at twenty-five. Husband alcoholic. Six living children, four miscarriages. Diastolic murmur at base, systolic at apex. Pulsation of abdominal aorta. Pupil reacts weakly to light. Tremor of fingers. Wassermann —.

Autopsy. Fibrous aortitis. Slight valvular endocarditis of aorta.

CASE II. Male, aet. 42 years. Aortitis, aortic aneurysm. Married at twenty-seven. Wife had miscarriage before her marriage and was said to be syphilitic. Some months after the marriage the patient presented secondary accidents without ever having noticed a primary sore. Wife had two miscarriages, no living children. Patient divorced and married again at the age of thirty-one. Second wife had two living children, one dying from meningitis. Also one miscarriage.

The second heart sound was clanging. Oliver's sign present; patellar reflexes brisk. Radioscopy: left-sided ampullar dilatation of aorta. Wassermann +.

Autopsy. Syphilitic aorta. Aortic aneurysm.

CASE III. Male, aet. 54 years. Specific aortitis with a double murmur. Patient's wife has been in insane hospital for eighteen years. One healthy daughter. Syphilis thirteen years ago. Polyarticular rheumatism. Double murmur at cardiac base. Pulsatile expansion. The aorta can be perceived in the suprasternal fossa. Pulsation of carotids. Confused psychism. Instant restlessness. Myotic pupils, reaction almost nil. Tremor of tongue and fingers. Wassermann—in cerebrospinal fluid.

*From the Medical Clinic of the University of Geneva.

GROUP II.

CASE IV. Female, aet. 57 years. Aortitis, slight aortic insufficiency, cerebral syphilis. Married at thirty-one. Husband in good health. One child who died from meningitis at the age of thirteen. Six miscarriages. Systolic and diastolic murmur at base. Unequal pupils, reflexes normal. Mediocere psychism. Epileptic paroxysms.

Lumbar puncture = albumin, 0.10 per cent; globulin, 0. Figured elements, 2.4 per cubic millimeter. Blood and cerebrospinal Wassermann +.

Autopsy. Very marked patches of aortitis throughout the aorta.

CASE V. Female, aet. 47 years. Specific aortitis. Married at seventeen. Husband neuropathic. One child who died at thirteen months from convulsions. Aortic symptoms. Few peripheral symptoms; tracings show that penetration is difficult. Right radial pulsates more strongly than the left. Tremor of tongue and eyelids. Wassermann +.

CASE VI. Female, aet. 67 years. Generalized arteriosclerosis; aortic insufficiency. Father died of apoplexy. Husband died with paralysis. Nine children, six of whom are dead; three were born at seven and a half months. No rheumatism. Double aortic murmur. Carotids greatly dilated with very strong beats. Radials synchronous. Tremor of legs and hands. Wassermann +.

Autopsy. General arteriosclerosis. Aortic valves thickened and indurated. Cylindrical aneurysm of ascending aorta.

CASE VII. Male, aet. 59 years. Double aortic lesion. Two healthy children. No rheumatism; no venereal infection. Double aortic murmur distinct at base. Duroziez's sign present. Weak reflexes. Wassermann +. Radioscopy: enlarged aorta, the arch extends high up.

Autopsy. Fibrous aortitis. Aneurysm of aorta. Old aortic and mitral endocarditis.

CASE VIII. Female, aet. 65 years. Aortitis with double aortic lesion and mitral insufficiency. Married at twenty-eight. Husband died of heart disease. One miscarriage. Mild muscular rheumatism. Double aortic murmur. Pulsatile expansion. Indistinct peripheral symptoms. Nervous system normal. Wassermann +.

Autopsy. Sclerosis of aorta. Dilatation and degeneration of the heart.

CASE IX. Male, aet. 62 years. Diffuse aortitis. Double aortic lesion. Married at eighteen. Wife had seven children and three miscarriages. Cause of wife's death unknown. Remarried; second wife had two children and two miscarriages. Denies syphilis. Double aortic souffle. Duroziez's sign present. Pulsation of carotids. Tremor of eyelids. Wassermann +.

CASE X. Male, aet. 64 years. Unmarried. Specific aortitis; aortic insufficiency with mild regurgitation. Denies all venereal contagion. Double aortic souffle; Duroziez's sign indistinct. Pigmentary spots on right flank (syphilides). Pupils unequal. Reflexes decreased. Romberg's sign present. Wassermann +. Cerebrospinal fluid under high tension; traces of albumin.

Autopsy. Fibrous aortitis with a little sclerosis. Slight chronic endocarditis of the aortic valves.

CASE XI. Female, aet. 50 years. Specific aortitis. Aortic regurgitation and insufficiency. Mother died in insane hospital with an apoplectic seizure. Married at eighteen; no children, no miscarriage. Double aortic souffle. Corrigan's sign. Left radial pulse precedes the right. Duroziez's sign. Pulsation of carotids and abdominal aorta. Increased patellar reflexes. Commencement of Babinski's sign. Wassermann +.

Autopsy. Fibrous aortitis. Sacciform aneurysm of beginning of aorta projecting into and perforating the esophagus.

CASE XII. Male, widower, aet. 63 years. Specific aortic insufficiency. Parents unknown. Married at thirty-three. Three children who all died very young in convulsions. No venereal infection. Second sound whistling and scrappy. Pulsatile expansion. Patient very nervous. Patellar reflexes absent, Achilles reflex increased. Wassermann +.

CASE XIII. Male, aet. 64 years. Specific aortitis. Aortic insufficiency and regurgitation. Married at twenty-seven. Four children, two died between the ages of one and two years. Wife died of pulmonary TB. Remarried at sixty-one; no children. Denies

syphilis. Double aortic souffle. Slight pulsatile expansion when lying on left side. Duroziez's sign present. Myosis. Weak pupil reaction to light. Patellar reflexes smart. Radioscopy: dilatation of aorta *en masse*. Wassermann +.

CASE XIV. Female, aet. 33 years. Specific aortitis. Married at twenty-three. Husband in good health. No children, no miscarriage. Denies venereal infection. Second sound accentuated. Tremor of eyelids. Sharp patellar reflexes. Wassermann +.

CASE XV. Male, aet. 47 years. Specific aortitis? Remains of hemiplegia and aphasia. Married at twenty-nine. Seven healthy children. Wife had one miscarriage (twins). Ictus three years ago, with hemiplegia and aphasia. Denies venereal infection. Arteries hard. High tension. Pulse stronger on right than left side. Second sound ringing at base. Reflexes increased. No Babinski even on diseased side. Wassermann +.

CASE XVI. Male, aet. 72 years. Aortitis. Married at twenty-three. Wife died after a miscarriage (second one). Four living children. Remarried at forty. Four children and two miscarriages by second wife. Divorced and remarried for the third time at sixty-six. Third wife had no children or miscarriages. Pulsatile expansion when lying on left side. Pulsation of carotids. Pulse tense, arteries hard. Very nervous. Wassermann +.

CASE XVII. Female, aet. 47 years. Specific aortitis; pleurisy. Married at twenty-two. Husband died at forty in insane hospital. Two children died in early life, two miscarriages. No rheumatism. Double souffle at base. Capillary and venous pulse. Weak pupil reaction to light. Wassermann +.

CASE XVIII. Male, aet. 69 years, unmarried. Specific aortitis; aortic insufficiency. No rheumatism. No venereal disease. Double souffle over aortic foci. Second sound more marked. Bounding pulse (Corrigan). Capillary pulse. Patellar reflexes absent. Myosis. Pupil reaction to light abolished, weak to accommodation. Wassermann +.

CASE XIX. Female, aet. 55 years. Aortitis with aortic insufficiency and regurgitation. One illegitimate child at twenty. Had three love affairs. Finally married at fifty, no children or miscarriages. Denies venereal infection. Double souffle at the base, more marked at systolic. Commencement of Duroziez's sign in the femoral artery. Nervous system normal. Radioscopy: ectasis of aorta. Wassermann +.

CASE XX. Female, unmarried, aet. 30 years. Aortitis and multiple arteritides. Two healthy children. No miscarriage. Pulsations of abdominal aorta can be detected. Nervous system normal. Wassermann +.

CASE XXI. Male, aet. 72 years. Aortitis. Aneurysm of the aortic arch? Married three times. Two daughters by first wife, one of whom died of meningitis. The second and third wives had neither children nor miscarriages. Pulse tense, more marked on left. Subclavian can be felt with each systole. Second sound accentuated at the base. Nervous system normal. Radioscopy: aorta covered by a shadow extending beyond it on the left. Wassermann +.

CASE XXII. Female, aet. 53 years. Chronic aortitis (specific?). Father alcoholic; one brother died of meningitis while a sister is affected with delirium of persecution. Married at twenty-five. Seven children, no miscarriage. Systolic souffle at the base. Patellar reflexes slightly increased. Radioscopy: broad aorta. Wassermann +.

CASE XXIII. Male, aet. 63 years. Abdominal aortitis; arteriosclerosis. Married at thirty. Seven children, six of whom died from diseases whose nature was unknown. Gonorrhea but not syphilis. Clang of second sound very marked at the base. Epigastric pulsation. Arteries hard; temporals sinuous. Nervous system normal. Wassermann +.

CASE XXIV. Male, aet. 48 years. Chronic aortitis, aortic insufficiency. Wife has had one child and one miscarriage. Diastolic souffle at base extending into the vessels of the neck. Second sound clapping. Substernal aortic dullness. Nothing noted in the nervous system. Wassermann +.

CASE XXV. Female, aet. 50 years. Aortitis, myocarditis. Rheumatism at seventeen. Married at twenty-two, was divorced six years later. One healthy

daughter; another daughter died at the age of thirteen "after taking cold." Irregularity in the intensity of the pulses. The aorta beats in the suprasternal fossa. Tachycardia. At the base there is perhaps a double soufflé partially concealed by the tachycardia. Nervous system normal. Wassermann —.

Autopsy. Recurrent aortic and mitral valvular endocarditis. Dilatation of the heart.

CASE XXVI. Male, aet. 57 years. Aortitis; aneurysm of the aorta. Second sound somewhat sharp and on the back can be heard down to the sacrum. The abdominal aorta can be seen to pulsate. Tremor of eyelids and tongue. Radiography: the aorta, especially the arch, is enormous and pulsating. Wassermann —.

Autopsy. Aneurysm of the aortic arch with perforation into the esophagus. Sclerosis of the aorta and arteries.

CASE XXVII. Female, aet. 67 years. Aortitis; general arteriosclerosis; right hemiplegia; aphasia; multiple foci of cerebral softening. Married at twenty-seven. Husband died at fifty-four from apoplexy. Two children; no miscarriages. Second sound hard. The aorta can be felt in the suprasternal fossa and in the abdomen. Femorals large and hard. Phenomena of high blood pressure. Pupils unequal. Reflexes increased. Babinski's sign on right. Wassermann —.

CASE XXVIII. Male, aet. 47 years. Double aortic lesion. Alcoholic. No children. Denies venereal infection. Inequality of the radials. Recurrent pulse on both sides. Systolic soufflé at base and a slight diastolic one. Duroziez's sign present. Capillary pulse. Nervous system normal. Wassermann —.

Autopsy. Aortic valves rigid, immovable, covered with calcareous deposits filling the valvulo-aortic sinuses.

CASE XXIX. Female, aet. 71 years. Aortitis from atheroma. One healthy daughter. Rough soufflé at base extending everywhere, even to the back. Radioscopy: Aortic shadow broad and high up. Wassermann —.

CASE XXX. Male, aet. 58 years. Aortic heart. Has had acute articular rheumatism. Two children. Clapping second sound. Pulsatile expansion. Duroziez's sign present. High blood pressure—19 with Riva-Rocci. Nervous system normal. Wassermann —.

Autopsy. Aortic endocarditis, with slight adhesions of the valves.

CASE XXXI. Male, aet. 43 years. Aortitis; aortic regurgitation. Married at twenty. Wife died from a tumor in neck. One son in good health. No rheumatism. Mesosystolic soufflé above the aortic focus. Nervous system normal. Wassermann —.

Autopsy. Old calcified endocarditis of sigmoid valves. CASE XXXII. Male, aet. 66 years. Specific (?) aortitis; aortic insufficiency and regurgitation. Double aortic soufflé. Pulsatile expansion. Pulsation of aorta can be felt in the suprasternal fossa. Pulsating carotids. Duroziez's sign present. Nervous system normal. Wassermann —.

Autopsy. Aneurysm of aorta. Cardiac dilatation.

CASE XXXIII. Male, aet. 41 years. Aortitis; aortic insufficiency. Married at twenty-eight, afterwards divorced. Two healthy children. No rheumatism or syphilis. Cardiac shock diffuse. Second sound doubled and whistling. Venous pulse. Tremor of fingers and tongue. Wassermann —.

CASE XXXIV. Female, aet. 51 years. Specific (?) aortitis. Twice married. Two children by first husband, no miscarriage. No rheumatism. Radioscopy: Pulsating dilated aorta. Double soufflé at the base. Bounding carotids. Duroziez's sign present. Nervous system normal. Wassermann —.

Autopsy. Fibrous aortitis. Chronic aortic endocarditis.

CASE XXXV. Female, 44 years. Aortitis, arteriosclerosis, angina pectoris. Father died at forty-seven from apoplexy. Rheumatism. Arteries hard. Pulse can be felt better on left than right side. Sharp second sound at base. Reflexes almost absent. Paroxysm of angina pectoris. Wassermann —.

CASE XXXVI. Female, aet. 58 years. Specific (?) aortitis. Father died from apoplexy. Married at twenty-eight. One child, died at the age of twenty-eight days, cause unknown. Double soufflé over aortic foci. Second sound accentuated. Intense carotid

shock. Aortic pulsation at the level of sternal fourth. Wassermann —.

Autopsy. Syphilitic aortitis with aneurysm.

GROUP III.

CASE XXXVII. Male, aet. 69 years. Aneurysm of aorta. Married at twenty-seven. Two healthy living children; two others died in early life, cause unknown. Wife had two miscarriages. Denies syphilis. Sharp second sound. Radial arteries unequal, hard. Pulsation of subclavians which are enlarged and raised, especially on the right. Reflexes very sharp. Wassermann —.

Autopsy. Fusiform aneurysm of thoracic aorta. Fibrous aortitis.

CASE XXXVIII. Female, aet. 66 years. Anomaly or arterial aneurysm. Husband alcoholic. Three children. Systolic soufflé at base, extending to left clavicle, axilla and back. Venous pulse. Extreme myosis. Absence of pupil reaction. Patellar reflexes weak. Wassermann —.

CASE XXXIX. Male, aet. 52 years. Aneurysm of aorta. No children. No rheumatism; denies venereal infection. Sharp second sound. Base of heart enlarged (percussion). Nervous system normal. Wassermann —.

Autopsy. Aortitis. Arteriosclerosis. Sacciform aortic aneurysm.

GROUP IV.

CASE XL. Female, aet. 74 years. Atheroma; mitral insufficiency. Systolic soufflé at apex. Indefinite shock with hard diastolic vibration in mid-cardiac area. Sharp second sound. Hypertension and hard pulse (Riva-Rocci, 18.5). Nervous system normal. Wassermann —.

CASE XLI. Female, aet. 65 years. Arterial sclerosis. Seven children; three died in early life; one miscarriage. Second sound slightly sharp. Pulsatile expansion. Rather high tension. Aorta perceptible in epigastrium. Nervous system normal. Wassermann —.

CASE XLII. Female, aet. 51 years. Multiple syphilitic arteritides. Married at twenty-three. Two healthy children, three miscarriages. Divorced and remarried at thirty-six; had no more pregnancies. Rheumatism at forty. Sharp second sound. Pulsation of aorta in suprasternal fossa. High blood-pressure. Unequal radial arteries. Tremor of tongue and fingers. Reflexes sharp. Clonus of right foot. Wassermann in blood +; cerebrospinal fluid Wassermann —.

CASE XLIII. Female, aet. 89 years. Atheroma. Myocarditis. Husband died of old age. Two healthy girls, five sons who died between the ages of 6 and 38 years, the youngest in convulsions. Irregular arrhythmia. Hard sounds, especially marked over base. Nervous system normal. Wassermann —.

Autopsy. Cardiac hypertrophy. Traces of old aortic endocarditis. Fibrous aortitis and arteriosclerosis.

CASE XLIV. Female, aet. 72 years. Arteriosclerosis. Arteries indurated. Nervous system normal. Wassermann —.

CASE XLV. Male, aet. 72 years. Atheroma. Multiple aneurysms. Prolonged shock of heart. Sharp second sound. Radials small, femorals large. Pupils unequal, parietic. Patellar reflexes exaggerated. Babinski's sign on left side. Peculiar psychism. Wassermann —.

CASE XLVI. Female, aet. 60 years. Single. Arteriosclerosis, alcoholism, epileptiform seizures. Arteries indurated. Heart sound clear. Patellar and Achilles reflexes almost nil. Restless. Cerebrospinal fluid slightly cloudy. Wassermann —.

These forty-six cases have, for clearness, been divided into four groups. The first comprises the aortic cases in which syphilis was known to exist, the second, those in which the patients denied venereal infection. The third group is composed of cases of aneurysm, while the fourth comprises patients presenting various aortic lesions—arteritis, atheroma, arteriosclerosis.

Group I: Aortitis in syphilitics = three cases.

Wassermann + in two cases.

Wassermann — in one case.

Group II: Aortitis in subjects unaware of any syphilitic infection = thirty-three cases.

Wassermann + in twenty-one cases.

Wassermann — in twelve cases.

Group III: Aneurysm of aorta, syphilis denied = three cases.

Wassermann + in all three.

Group IV: Atheromatous lesions of aorta, syphilis denied = seven cases.

Wassermann + in three cases.

Wassermann — in four cases.

Briefly stated, out of forty-six subjects with disease of the aorta, only three admitted syphilitic infection, all others—forty-three in number—denied it or at least did not suspect having it.

Of these forty-three patients, twenty-seven gave a positive Wassermann. It is true that in going into the antecedents of these twenty-seven subjects, twenty are clinically suspicious since they presented nervous disturbances, polymortality of their children, absence of offspring, miscarriages, etc. Eliminating these twenty cases (74.07 per cent.) seven others nevertheless remain (25.92 per cent.) who gave no suspicion of syphilis, yet in spite of this fact fixation of the complement in the blood was positive.

The patients of Group I need not be discussed, since they were known to have syphilis, but if we take up Group II, consisting of thirty-three patients who denied any venereal affection, we find that there were twenty-one presenting a positive Wassermann. Of these twenty-one there were fifteen who offered in their clinical history nervous phenomena or psychic symptoms and in which syphilis was confirmed by autopsy. Nothing could be found in the remaining six, either in their antecedent or clinical condition, which could lead one to admit this etiological factor. It is to be noted that of these six patients (cases XIX-XXIV) three were males and three females and that all excepting one (case XX) were over forty years of age. And lastly, in the majority, besides their signs of aortitis, the radials and temporals were hard and tortuous.

The third group comprises three cases of aneurysm with a positive Wassermann in all. Two of the patients denied syphilis (cases XXXVII and XXXIX), but the absence of offspring in one (case XXXIX) and death of the children in early life in the other (case XXXVII) is sufficient to admit that there was luetic infection. As to the third case (case XXXVIII) the existence of syphilis is not stated, but the absence of reaction of the pupils and weak patellar reflexes are noted.

In the fourth group three patients out of seven gave a positive Wassermann in the blood. One patient (case XL), however, gave nothing in the clinical history that might lead to the suspicion of syphilis. As to two others, one (case XLI) lost three children in early life (one at the age of two months from convulsions), the other (case XLII) had three miscarriages and presented disturbances of the nervous system.

It would be assuming too much to oppose the general idea that almost all aortitides are due to syphilis. Nevertheless, I am convinced that not a few aortic lesions, regarded until now as specific

simply because the fixation sero-reaction is positive, are not in reality the result of syphilis. This applies especially to atheromatous lesions in elderly subjects even when the Wassermann is positive. I am more than positive that we should not place undue confidence in sero-reaction in these circumstances, because as Prof. Bard maintains, aortitis and atheromatous patches are perfectly susceptible in themselves, of creating antibodies capable of fixing the complement, since this cannot be regarded as a specific reaction.

THE DIAGNOSIS OF INTRATHORACIC NEOPLASMS.*

BY MATRICE FISHBERG, M.D.,

AND

M. STEINBACH, M.D.,

NEW YORK.

(FROM THE TUBERCULOSIS DIVISION OF THE MONTEFIORE HOME AND HOSPITAL FOR CHRONIC DISEASES.)

DURING the past five years thirty-three cases of primary malignant neoplasms of the bronchi, lungs, and pleura have been admitted to the Montefiore Hospital. This appears to be a larger number than any other hospital has reported within such a comparatively short period, and we were at first inclined to attribute it to our diligence in looking for this class of cases. The fact that of the thirty-three cases admitted, only four were diagnosed correctly before admission to the Montefiore Hospital appeared to speak in favor of such a view. But further inquiry points altogether in another direction.

There appears to have occurred an increase in the absolute, as well as the relative, number of cases of primary malignant neoplasms of the lungs. This increase has, however, been noted mainly by pathologists while making autopsies; most cases had been otherwise diagnosed during life. Statistics published from the various pathological laboratories in Europe are to this effect, and in this city, Dr. Douglas Symmers informs us that in the twelve years previous to July 19, 1919, he encountered five examples of primary malignant neoplasm of the lungs in the Pathological Laboratory of Bellevue Hospital, and from July 19, 1919, to December 20, 1920, he saw eight cases.

Of the thirty-three cases that have been observed at the Montefiore Hospital during the past five years, complete autopsies have been obtained in sixteen, and in three surgical autopsies. It is worthy of mention that in all but one the diagnosis was made during the life of the patients, while in only one case was the diagnosis of the disease found at the autopsy to be an error. It is our conviction that the cases on which this communication is based were diagnosed during life of the patients because we relied mainly on purely clinical methods, on the history, symptomatology, course, and physical signs, while other diagnostic and laboratory methods, such as cytology of excretions and exudates, and radiography, were invariably considered as of merely confirmatory importance.

Nearly all our patients, before admission to the Montefiore were in other hospitals or clinics, where

*Read before the Section of Medicine, New York Academy of Medicine, February 15, 1921. (For discussion, see page 540.)

efforts at making a diagnosis had been made. The result was that the thirty-three patients were referred to us with the following diagnoses: Cancer of the lung, 4; pulmonary tuberculosis, 13; pleurisy with effusion or empyema, 7; chronic pneumonia, 2; cardiac disease, 2; neurosthenia, 1; abscess of the lung, 2. Despite this variety of diagnoses on admission, in two-thirds of the number of cases we either diagnosed tumor of the lung at the first examination of the patients, or at least suspected it. The purpose of this communication is mainly to show how we are led to make this diagnosis; the details of these cases will be given in a later communication.

It seems that malignant growths of the lung are so often missed because it is considered an exceedingly rare disease, and is never thought of when an atypical case of some more common pulmonary disease is examined. The fact that the onset is insidious, with cough, expectoration, pain in the chest, dyspnea fever, hemoptysis, and that the physical signs are usually those of a localized airless area of lung tissue, is responsible for the large number that are mistaken for pulmonary tuberculosis. In 50 per cent. of cases pleural effusions, serous, sanguineous, or purulent, occur; and for this reason, a large proportion are treated as pleurisy. In the later stages, when the tumor disintegrates, cavities are formed in the lungs, and fetid sputum is expectorated, thus abscess or gangrene of the lung is simulated. However, a careful scrutiny has shown that nearly all cases have certain characteristic traits which betray the presence of a new growth in the chest, provided it is always borne in mind that this disease is a possibility in all aberrant chronic pulmonary conditions in persons of the cancer age.

Nearly all patients with malignant growths in the chest cough and expectorate sputum which is not unlike that brought out by tuberculosis patients. Of course, no tubercle bacilli are found on repeated examinations. But in about one-half the number, hemoptysis was an early symptom. At first the blood is scanty, though the streaky sputum of phthisis is rare. Usually the sputum is thoroughly mixed with blood, and it thus presents the appearance of raspberry juice or current jelly. In the later stages, when disintegration of the tumor takes place, there may be copious and uncontrollable pulmonary hemorrhages; one of our patients succumbed to such a hemorrhage.

But there are two early symptoms which are hardly ever seen in early phthisis, namely, dyspnea, and pain in the chest. *It is important to think of a pulmonary neoplasm when a patient in the cancer age, showing no symptoms of cardiac, renal, or arterial disease, begins to cough, and is short winded.* In the advanced stages of tuberculosis severe dyspnea is at times encountered, but then the history and physical signs show extensive destruction of lung tissue, a pleural effusion, or a pneumothorax. The dyspnea in cancer is due to the plugging of a large bronchus from within or from without; when a primary bronchus is thus obstructed by the growth, or the trachea is pressed upon, the dyspnea may be severe, agonizing. Sudden death from asphyxia has thus occurred in two of our cases. Other pressure phenomena seen in

lung tumors include pressure against the large veins, especially the superior vena cava, when the tumor extends into the glands of the mediastinum along the lymphatics. The result may be edema of the upper part of the chest, neck, and face. In some cases the tumor extends into the right ventricle, or is pressing against it, producing intense dyspnea, cyanosis, edema of the entire body, etc. Pressure against the esophagus may result in difficulties in deglutition; in two of our cases it led to inanition. We have had cases in which the dyspnea was paroxysmal, owing to pressure which was more or less relieved on moving the body in certain directions. Stridor is very rare; we encountered it only in three of the thirty-three cases.

Pain, next to dyspnea, is a constant symptom; it was present more or less in thirty-one out of our thirty-three cases. It is usually felt in the lower part of the chest, in the axillary region, and in the shoulder, radiating to the arm, forearm, even to the finger tips. It is frequently misinterpreted and ascribed to pleurisy or intercostal neuralgia. However, the acute onset, friction sound, etc., of acute pleurisy are absent. In pleurisy with effusion, the pain is ameliorated, or disappears after an effusion takes place, while in tumor it remains after an effusion occurs, or may even become more pronounced. *In patients who have passed middle age, pain in the chest, with or without a pleural effusion, is suggestive, and requires careful investigation.*

In attempts at differentiation from pulmonary tuberculosis we are at times baffled because of fever which occurs in the majority of cancer cases very early, and in many even night-sweats have been noted. The fever may be mild, running up to over 100° Fahr. in the afternoon and normal during the morning. It may be high in the later stages, 103° to 104° Fahr., continuous, remittent, or intermittent. This in patients with cough, profuse expectoration, hemoptysis, etc., showing signs of a localized lesion in the chest, exquisitely simulates advanced pulmonary tuberculosis. It is for this reason that so many cases were sent in to us with that diagnosis. But in that vast majority of cases physical exploration of the chest decides the diagnostic problem.

Enlargement of the superficial glands is a late symptom, and when this is found the tumor in the lung is, as a rule, quite extensive. These glands are usually found on the neck, between the heads of the sternomastoid, and require careful palpation to be elicited as small hard nodules, freely movable. When at a later stage the glands are very large and visible on inspection, the axillary glands are also found enlarged. Only in rare and far advanced cases are the inguinal glands enlarged, indicating extensive metastasis. Enlargement of the superficial veins of the chest and shoulder is seen only in cases in which metastasis has occurred into the mediastinal glands, and this is uncommon.

The diagnosis is made by physical exploration of the chest and, in our experience, it has been more often decisive than any other diagnostic method. In many cases a small tumor nodule is more easily and much earlier discerned by percussion and auscultation than by radiography. We have mainly relied on the flat note elicited by percussion over the site of the tumor, and the flat area is, as a rule,

much more extensive than the size of the growth, because it obstructs a bronchus, thus cuts off the air supply of the lung supplied by that tube. This flatness is found in the upper lobe of the lung, or runs across the chest—is suspended—or is elicited over the lower lobe of the lung, according to the location of the tumor and the bronchus it obstructs. In a few cases, when the tumor does not obstruct a bronchus, it may be found by percussion, which shows a flat area extending a few inches away from the border of the sternum anteriorly, or from the spine posteriorly. At times we found flatness anteriorly, while posteriorly the note was normal or even hyperresonant.

Flatness in the lower parts of the chest commonly denotes pleural effusion, or a thick pleura; in the upper lobe it simulates a tuberculous lesion. But tuberculous lesions of the upper lobe emit a dull note, never a flat one. This is always to be borne in mind.

Auscultation will show feeble, or complete absence of breath sounds when a bronchus is obstructed. It is noteworthy that this may be found in cases with very small growths, provided a large or medium sized bronchus is obstructed, which is true of a very large proportion of cases. In cases in which the growth is in the region of the upper lobe the absence of breath sounds shows that we are probably not dealing with a tuberculous lesion in which the note is never flat, and there are nearly always audible some altered breath sounds, bronchovesicular, bronchial, or cavernous. In cases with flatness running across the middle of the chest, or involving the lower half of the chest, absence of breath sounds points to pleural effusion, either interlobar or general. The absence of adventitious sounds shows that in upper lobe cases we are not dealing with tuberculosis, while in middle and lower lobe cases it again points to pleural effusion. The same is true of the vocal fremitus, which is feeble, or more commonly absent over the affected area. However, the history of the case is usually sufficient to rule out pleural effusion: the acute onset is lacking and the persistence or aggravation of the pain in the chest, despite the evidences of fluid, points to a tumor.

In many cases the growth does not completely compress a bronchus, but only narrows it, and air is still permitted to pass through the narrowed tube. Here we get bronchial, or even amphoric breath sounds, which has been called by some writers *cornage*. When heard near the border of the sternum, or in the interscapular space, especially its upper half, in a patient in whom the note over the upper lobe of the lung is flat on percussion, and no adventitious sounds are audible, it is characteristic of tumor of the lung. It simulates a cavity, but the flatness and the absence of adventitious sounds point to a tumor.

Many lung tumors break down, and the patients expectorate large masses of sputum, have profuse hemorrhages, run high fever, sweat, etc. In these cases signs not unlike those of tuberculous cavities are elicited on physical examination, and, in fact, most of them are treated for tuberculosis. However, of the 15 cases of this type that have been sent in to the Montefiore Hospital as tuberculous, nearly all were differentiated within a few days

after admission. We have relied on the following diagnostic criteria: The history of the cases, the fetid sputum lacking in tubercle bacilli, the freedom of the opposite lung from signs of pathological changes, the flatness of the percussion note, etc., all point in the direction of a tumor. In doubtful cases the induction of an artificial pneumothorax and the taking of a radiogram may clear up the diagnosis, as has been described elsewhere. (See *Journ. Amer. Med. Assn.*, 1921, lxxvi, p. 581.)

With the appearance of pleural effusion, which occurs in over 50 per cent. of cases, things change and the difficulties in diagnosis multiply. Signs of the effusion are easily detected and a favorable prognosis is given. If exploratory puncture reveals pus, an operation is resorted to and the surgeon wonders why, after weeks of careful draining, there seems to be no tendency for the lung to expand and the wound to heal.

Experience with a comparatively large number of these cases has taught us that effusions secondary to pulmonary neoplasms have certain characteristics which betray the new growth. It seems that in these cases the fluid accumulates very rapidly and completely fills the chest. Inflammatory effusions, on the other hand, fill only part of the chest and rarely reach above the fourth or third rib. For this reason, in inflammatory effusion percussion shows a lower zone of flatness above which the resonance is slightly tympanic—Skodaic. When there is a tumor behind the effusion, or when the growth originates in the upper lobe of the lung, a flat note is elicited all over the affected side of the chest, from above the clavicle to the lower margin of the thoracic wall. *It is important to think of a lung tumor when one side of the chest is flat and offers the characteristic resistance to the pleximeter finger from the clavicle to the base.* Likewise, absence of breath sounds over one entire side of the chest, excepting cornage mentioned above, if not due to a pneumothorax, which is excluded by percussion, is almost invariably due to a tumor of the lung or pleura with an effusion.

In cases presenting these signs careful investigation will usually reveal other symptoms and signs confirmatory of the pathological process in the lungs—enlarged glands will be found on the neck, the mediastinum will be found displaced, though in shrinking tumors of the pleura it may be drawn toward the affected side; pain in the chest will be complained of, which cannot be accounted for by the more common clinical conditions.

In attempting differentiation from more common diseases of the lungs and pleura, the following points have proven of value: Enlarged glands of the neck may be due to cancer of the lung, tuberculosis, or Hodgkin's disease. Hodgkin's is differentiated along the usual lines of diagnosis of this disease. But tuberculous glands have one characteristic which, if borne in mind, will spare many errors: *Patients with enlarged tuberculous glands on the neck hardly ever have signs of active disease in the lungs, while when the glands are malignant we find signs of extensive changes in the lungs.* Dense consolidation of lung tissue, revealing itself by flatness, absence of breath sounds, etc., is an indication that the enlarged glands on the neck are malignant, and not tuberculous.

Many cases have been admitted with symptoms and signs of abscess or gangrene of the lung, and the signs elicited by physical examination apparently confirmed these diagnoses. However, abscess and gangrene of the lung are almost invariably preceded by some acute inflammatory disease of the lung, especially pneumonia, or by the aspiration of a foreign body. They have a history of sudden onset with a definite symptomatology. When the fever, cough, and expectoration of fetid sputum are due to a disintegrating cancer of the lung, a history of an insidious onset will be obtained. We have found it expedient to suspect all cases of "abscess of the lung" in persons of the cancer age of malignant disease of the lung, and to delve carefully into the history, symptomatology, and course of the disease, while the physical signs usually clinch the diagnosis.

We have made use of nearly all the laboratory aids in diagnosis, and found them in a few instances confirmatory of the clinical findings, but in most cases they prove either of no value or altogether misleading.

In three cases cancer cells were found in the sputum. But only when the tumor disintegrates, and parts are expectorated will these cells make their appearance in the sputum, and this is rather late for a diagnosis. Routine clinical methods prove decisive much earlier, as we have shown.

Moreover, cells not unlike those of malignant tumors may be found in the sputum expectorated by patients suffering from any disease of the bronchi, lungs, or throat. The large number and variety of epithelial cells which are derived from the epithelial linings of the mouth, nose, throat, and bronchi, and some, even, from the esophagus, may deceive the most competent pathologist. In fact, in most cases in which we have sent the sputum to the pathologist for intensive study of its cytology, his report has invariably been rather guarded, which did not permit absolute reliance, such as is given in a report of the finding of a specific organism.

Likewise, examination of the pleural exudate has been of but little value. It is very frequently sanguineous. Of 21 effusions, 4 were sanguineous. This is not a very high proportion, and when we consider that it is sanguineous at times in tuberculous effusions, its diagnostic significance wanes. However, in persons over 35 with a history of an insidious onset and pain in the chest, dyspnea, etc., it is suggestive. It may be purulent: in 5 of our cases it was so. Examination of the sediment of the fluid obtained by exploratory puncture has also given us but little help in diagnosis. Hardening the sediment and cutting and staining it have been attempted in several cases. But a comparison of findings with those obtained in tuberculous pleuritis hardly shows any difference. In two cases the cytology was suggestive of cancer cells, but it was never conclusive.

Of greater utility has been found radiography in lung tumors, but in many cases it proves misleading or negative. In the vast majority of cases it could not be considered of final value. A small tumor may altogether escape registration on the plate. In 2 cases of extrathoracic cancer, physical exploration of the chest revealed physical signs

strongly suggestive of metastatic deposits in the lungs. The radiographic plate taken at that time showed nothing to lead one to suspect a tumor in the indicated area. But about 4 weeks later, when the tumor had grown, it was discovered on the plate. It is thus clear that a small tumor, provided it impinges on a bronchus, or grows within it, may be discovered by careful physical examination much earlier than the x-rays will clearly reveal it.

Moderate sized and large tumors appear clearly on the plate as homogeneous shadows, sharply defined. In some cases there is no line of demarcation, and then it may be easily mistaken for other pulmonary lesions. Now and then an interlobar effusion will exquisitely simulate a tumor of the lung. Likewise, miliary carcinomatosis cannot be differentiated from miliary tuberculosis on the plate. When fluid appears, and it does in over 50 per cent. of cases, it covers up the tumor and the radiographer can only report an effusion. This, in fact, is the source of a large proportion of errors in diagnosis. It appears, however, that when the shadow cast by the fluid fills the entire half of the chest, radiographers are justified in suspecting a tumor of the lung or pleura. But, after all, only the history and physical signs have proved decisive in our cases. Nearly all our cases of this sort went to the radiographer with the suggestion that we consider the possibility, or that we are convinced that there is a lung tumor.

We have resorted to the following procedures: Withdrawing the fluid and immediately taking a radiogram will show a tumor which is otherwise obscured by the fluid. Of late we withdraw the fluid and produce a pneumothorax, then a radiogram will show the tumor clearly and unequivocally.

NEW AND SIMPLE TESTS FOR ALKALINE CARBONATES IN URINE.

By CLIFFORD MITCHELL, M.D.,

CHICAGO, ILL.

For detecting the presence of alkaline carbonates in urine we have relied in the past, first, upon litmus paper, which shows that the urine is alkaline; second, upon effervescence of the urine when acids are added to it; third, upon the fuming which takes place, if ammonium carbonate is present, when a rod moistened with hydrochloric acid is held close to the urine, and, fourth, upon microscopic identification of certain crystals, as when triple phosphate or calcium carbonate is present in the urinary sediment. We have also been advised to dry the litmus paper, which has been turned blue, and to observe whether the blue color is permanent (fixed alkali) or whether it disappears (volatile alkali).

The writer has no wish to make adverse criticism of any of these older tests. The general practitioner can use now one, now another of them according as they are available, but most of them have been discarded by the writer himself, since the new tests, described in this article, have been discovered and perfected by him. These new tests do away with much that is inconvenient or disagreeable, and enable the physician to make bedside examinations of the urine without danger of soiling either hands or clothing.

The cleanest thing the practitioner can use for

urine testing is the ordinary medicine dropper. The new tests are so devised that they can be performed readily by the aid of this cheap and simple instrument.

To discover whether the urine contains alkaline carbonates: By means of a medicine dropper fill a small test tube half full of the urine to be examined and, using another medicine dropper or, preferably, a drop bottle, add to it a few drops (five are enough) of the writer's acid mercurous nitrate solution. Do not shake the tube, but see that the five drops lie on the upper stratum of the urine, holding the test tube by the closed end with the left hand. If alkaline carbonates are present in quantity sufficient to be of clinical significance, a dark precipitate will immediately be seen in the upper stratum of urine. If they are absent or only in traces, a white precipitate is seen. The dark precipitate in case of carbonates is likely to darken still more on standing.

The mercury solution is made by dissolving one gram of "mercury nitrate, mercurous," Merck, in 100 c.c. of distilled water. (Water decomposes mercurous nitrate into an acid nitrate, which goes into solution, and a basic nitrate which remains undissolved). Shake well and let stand for some hours; then decant or filter. In order to become familiar with the workings of the test, dissolve half a teaspoonful of sodium carbonate in a glass of water or normal urine and test this solution with the mercury reagent. Dilute the soda solution with different volumes of water and make the test upon the various dilutions, observing the color of the various precipitates.

The mercury solution also precipitates soluble sulphides, but these are not of common occurrence in the urine. The dark precipitate obtained, if it is not affected by adding 50 per cent. acetic acid (10 drops or more), is due to sulphides. If, however, the acetic acid turns the dark precipitate brown or gray, and it immediately settles, carbonates and not sulphides are present in the urine.

Certain drugs, especially when used intravenously, may interfere with the reaction one way or another; hence, care should be taken to test the urine at periods when no intravenous work has recently been done upon the patient.

The mercury solution keeps well, though a slight sediment gradually forms. It may be well to test it from time to time with dilutions of a sodium carbonate solution and, if it appears to deteriorate, to make up a fresh solution. Repeated weighings are not necessary, when fresh solutions are made, except for the sake of economy. The physician, having once become familiar with the volume of the crystals weighing a gram, can use enough of the salt each time to satisfy himself that plenty of the reagent is being added to the 100 c.c. of water.

The mercury test shows carbonates in the urine but does not differentiate them one from another. The urine may contain sodium carbonate or ammonium carbonate or, if sodium bicarbonate is taken by the patient, this substance may be present. Sodium phosphate taken by the patient does not appear to give a dark precipitate with the mercury reagent.

In order to differentiate ammonium carbonate from other carbonates, the mercury test, when posi-

tive, in the case of urine having an odor of ammonia, is sufficient. Indeed, the odor of ammonia alone, without the mercury test, suffices. But the writer finds that considerable ammonium carbonate may be present in urine before an ammonia odor sufficient to attract attention can be discovered, at least by the writer's olfactory sense, which is fairly acute. Inasmuch as ammonium carbonate is, on the one hand, pathological when occurring in freshly voided urine, and, on the other hand, troublesome chemically when occurring in urine after it has been voided, the physician should know whether this substance, in amount clinically significant, is present.

To detect ammonium carbonate in urine the writer uses Nessler's solution, which can be made either according to the formula described in the sixth edition of Hawk's Physiological Chemistry (Nessler-Winkler solution) or by means of the older formula described in Sutton's Volumetric Analysis, sixth edition.

The Nessler-Winkler solution is easier to make. It contains 10 grams of mercuric iodide, 5 grams of potassium iodide, and 20 grams of sodium of potassium hydroxide per 100 c.c. of water. The general practitioner can make it himself as follows: Procure an ounce of mercuric iodide (red iodide of mercury) and divide it into three equal portions; procure an ounce of potassium iodide and divide it into six equal portions; procure four ounces of sodium hydroxide, sticks, and divide them into six equal portions. Shake up one portion of the red iodide in two fluid ounces of distilled water, until it is well mixed; then add one portion of the potassium iodide and shake well until it is dissolved; finally dissolve two portions of the sodium hydroxide in an ounce of water and cool well; after it has cooled, pour it gradually into the mixture containing the iodides, and stir well. The mixture becomes clear and of light yellow color. It should measure about 3.33 ounces (100 c.c.). If it falls short, add more water. A flocculent precipitate soon forms, which should be allowed to settle, the supernatant liquid being poured off for use. If the physician has a centrifugal machine, the precipitate can be removed by centrifugation, the supernatant liquid being poured off for use in testing. The unused portions of the chemicals can be kept for another occasion or made up into solution according as is required.

The old formula for Nessler's solution contains 1.7 grams of mercuric chloride, 3.5 grams of potassium iodide, and 20 per cent. solution of sodium hydroxide sufficient to bring the solutions of chloride and iodide up to 100 c.c. Dissolve the mercuric chloride in 30 c.c. of water, warming to aid solution. Dissolve the iodide separately in about 10 c.c. of water. Add the cooled mercury solution, drop by drop, to the iodide solution until a precipitate forms which does not clear on shaking. Then dilute the mixture with 20 per cent. sodium hydroxide solution until it measures 100 c.c. Finally add what is left of the mercury solution until a permanent precipitate forms. Let settle and decant or centrifuge.

Whichever solution is made should be kept in a tightly stoppered bottle.

To make the test for ammonium carbonate take

up 1 to 3 c.c. of the reagent with a clean medicine dropper, or with a clean pipette as, for example, that used for delivering urine in the Doremus hypobromite test, and place it in a small test tube or 5 c.c. graduate. Then, using another clean medicine dropper, add to it, without shaking, from 2 to 5 drops of the urine to be tested. If ammonium carbonate is present, a red precipitate forms, which floats for a time on the surface of the mixture. If no ammonium carbonate is present, a yellow precipitate forms which soon darkens on standing. Urines containing sodium carbonate or bicarbonate are negative to this test when performed as above. If the urine contains much ammonium carbonate, one drop of it will show a marked red precipitate. The red precipitate can be plainly seen by looking into the tube from above.

To determine the quantity of ammonium carbonate, approximately, after its presence has been shown by the above test, proceed as follows: Pour into five clean glasses, beakers, or graduates 30, 60, 120, 240, and 480 c.c. of water, respectively, that is to say, 1, 2, 4, 8, and 16 fluid ounces. To each one of these add 1 c.c. of the urine in question, for which purpose the pipette used with the Doremus ureometer is convenient. Mix well, preferably by pouring back and forth into other clean glass vessels. Provide five small test tubes or 5-c.c. graduates and into each one pour 2 to 3 c.c. of the reagent. Then, using clean medicine droppers, float 2 or 3 c.c. of each of the mixtures on each of the reagent quantities in the test tubes. Urine containing a large amount of ammonium carbonate will show a marked red cloud at and above the juncture of the two fluids, even when diluted as much as 1 to 240 or possibly 1 to 480.

For clinical purposes, therefore, the amount of ammonium carbonate found from time to time may be designated by the figures 1, 2, 3, 4, or 5, according as the red cloud is present or absent on testing the dilutions. It goes without saying that absolute cleanliness is a desideratum in making these determinations, owing to the delicacy of the test.

(To float a dilution on the chemical solution hold the test tube containing the chemical almost horizontally and deliver the dilution from a medicine dropper or pipette as slowly as possible. Since urine of high specific gravity tends to darken quickly, if a small amount only of ammonium carbonate is present in it, it is well, in cases of doubt, to dilute the urine with one or two volumes of water and to repeat the qualitative test. If this is now plainly positive, then proceed with the quantitative test, as above described.)

By means of these tests, used as described, the degree of decomposition of the urine, taking place in the bladder, may be inferred from the amount of ammonium carbonate found, as in the case of prostatics. If ammoniacal decomposition has also taken place in the pelvis of the kidney, a quick and ready test is provided for urine withdrawn by means of urethral catheterization, since only small quantities of urine are needed for such a test. In the case of patients unable for any reason to void more than a few drops of urine the test is particularly useful, since not more than five or ten drops of urine may be required.

Lastly, for determining whether the urine has

become stale from exposure to the air, as in a warm room, the test is particularly valuable. Ammonium carbonate in urine interferes with acidity determination, with urobilin detection, with the volumetric quantitative determinations of uric acid and phosphoric acid, and nullifies to a great extent the value of microscopical examination of the sediment. Especially is ammonium carbonate in urine likely to cause fallacious analytical conclusions where the ratio of urea to ammonia is determined, as in the toxemias of pregnancy. Urines which in small quantities (one-five drops) produce a copious red precipitate with the Nessler reagent are, as a rule, not fit for analysis, in the sense that the results of such an analysis are not necessarily conclusive and may even be misleading.

To differentiate sodium bicarbonate in urine from sodium carbonate is, as a rule, of no great importance, since the patient usually knows whether he has been taking sodium bicarbonate or not. The writer has noticed that when the Nessler-Winkler reagent is used, five drops of urine containing sodium bicarbonate added to 3 c.c. of the reagent produces a yellow which quickly turns darker, while in the case of sodium carbonate the change may be slower and not so marked.

If ammonium carbonate has been excluded, and if in 10 c.c. of a urine a red color is produced when one or two drops of phenolphthalein indicator are added, sodium carbonate rather than bicarbonate is likely to be the alkali, and such urine will also turn red litmus blue. If, however, the urine turns red litmus blue and does not redden when to 10 c.c. of it are added one or two drops of the phenolphthalein, but requires addition of decinormal sodium hydroxide to produce the red, then sodium bicarbonate is likely to be the alkali.

The writer directs attention to the peculiar action of sodium bicarbonate with his acid mercurous nitrate reagent: if an aqueous solution of the bicarbonate be made and tested, it will be found that a dark precipitate may not occur, but a light-colored one, somewhat yellowish in hue. On the other hand, sodium bicarbonate dissolved in urine yields a dark precipitate when tested with the mercury reagent, just as do the other alkaline carbonates in urine. If the patient is taking potassium iodide, a dark precipitate may occur when the urine is tested with the mercury reagent.

In general, therefore, when these new tests are used it is advisable to suspend administration of alkalies for the time being, in order to be certain of results obtained. Alkalies not sufficiently purified may contain ammonium compounds yielding positive reactions with Nessler's solution.

The writer's experiments show that litmus paper cannot be depended upon as a negative test for ammonium carbonate, since urine containing an appreciable amount of this carbonate may perceptibly redden blue litmus paper. On the other hand, the fact that urine is neutral or alkaline to litmus does not indicate, necessarily, that ammonium carbonate or any carbonate is present.

The changes in the urine, which lead to the formation of ammonium carbonate, are such as are likely to result in the disappearance of important constituents of the sediment, as, for example, red blood corpuscles or tube casts, especially when but

few were originally present. Hence it becomes important for the clinician to become aware of the presence of ammonium carbonate in urine, to be able to form an opinion as to the quantity of it, and to differentiate it from other carbonates.

To do this quickly and accurately, without the use of acids, without causing production of foam or odor, without need of heating, without the use of any kind of papers, and without danger of soiling hands or clothing has been the desideratum for which the writer has striven in devising the new tests, above described, which require for performance quantities of urine in no case exceeding 5 c.c., and, for detecting ammonium carbonate, only a few drops.

Summary.—1. The presence of alkaline carbonates in the urine is inferred when a dark precipitate forms after addition of a few drops of a 1 per cent. solution of mercurous nitrate to a few cubic centimeters of the urine.

2. The presence of ammonium carbonate in urine is shown when a red precipitate forms after addition of a few drops of urine to a few cubic centimeters of Nessler's solution.

3. In the absence of ammonium carbonate a positive reaction with mercurous nitrate points to the presence of sodium carbonate or bicarbonate, the latter being inferred when the patient presents the history of having taken "soda bicarb." or baking soda recently.

4. Rarely a positive reaction with mercurous nitrate is due to soluble sulphides, in which case acetic acid (50 per cent.) does not change the color of the precipitate.

5. Drugs taken by the patient, especially iodides and intravenous medicaments, may lead to erroneous conclusions when the mercurous nitrate test is employed; hence, knowledge of what the patient is taking should always be had by the physician employing the test.

25 EAST WASHINGTON STREET.

THE ETIOLOGY OF MULTIPLE SCLEROSIS

(SPIROCHÆTOSIS ARGENTINENSIS).*

By W. H. HOFFMANN, M.D.,

HAVANA, CUBA.

As the researches of the last years have shown, an always increasing number of diseases are found to be caused by spirochetes of different kinds; and in many cases it has become evident that the spirochetes attack by preference the central nervous system, which is involved in the disease much more than, from mere clinical observation, formerly could have been supposed. In the same sense it seems now that multiple sclerosis belongs to this most important group of nervous diseases produced by spirochetes.

Multiple sclerosis (sclérose en plaques), since the middle of the last century, has been the object of many and intense studies, and all the details of the clinical symptoms are very well known, as well as the anatomical and histopathological features.

Though the symptoms may vary in the single cases in wide range, according to the different seat of the lesions in the brain and spinal cord, still there

*From the Laboratory of Medical Research, Las Animas Hospital.

are several classical signs of the disease which generally allow one to make an exact diagnosis even at an early stage. For that reason it has been possible to show that the affection is by no means rare, but is relatively often discovered by neurologists.

Hitherto very little was known as to the origin of the disease. Often it had been supposed that the causes must be sought in psychic, climatic, or poisonous influences and lesions. Repeatedly a possible connection with syphilis has been considered, which in fact can produce very similar symptoms; but the modern diagnosis of syphilis as by the Wassermann and other tests, did not support that view. On the other hand it has become lately more and more probable that some relation to previous acute infectious diseases often exists.

In 1917 Kuhn and Steiner (*Mediz. Klinik*, 1917, N. 18), reported, that they had succeeded in finding some spirochetes in connection with multiple sclerosis, which were different from the *Spirochæta pallida*, and resembled mostly the spirochete of Weil's disease, being perhaps still more delicate organisms than the leptospira. They made their observations in four cases, three of which were quite fresh, while in the fourth the disease had existed for two years, but showed symptoms of recent exacerbation. They injected blood and serum of these cases into guinea pigs and rabbits and found that the animals developed a disease which was fatal and could be transferred by inoculation to other animals. In the blood from the liver of the animals, two guinea pigs and three rabbits, they found spirochetes which were always lying in the interior of blood vessels, never in the tissues. It was not possible to find the spirochetes directly in the human organs.

In 1918 Siemerling found, by the darkfield, some similar spirochetes in the brain of a man who had died from multiple sclerosis (*Berliner Klin. Wochenschr.* 1918, N. 12). Also by observations of Simons it was confirmed (*Neurol Centralblatt*, 1918, N. 4), that rabbits could be successfully inoculated by the serum of a case which suffered from fresh inflammatory symptoms of multiple sclerosis. Formerly Bullock had reported successful inoculations of rabbits.

In 1919 Marinesco (*Rev. neurol*, 1919, p. 481), infected six guinea-pigs by intracerebral injection of 3 c.c. of serum from two cases, and was able to show by the darkfield the presence of a great number of living and motile spirochetes in the cerebrospinal fluid of the animals, which he had taken by puncture of the fourth ventricle. The animals had presented difficulties of locomotion almost similar to paralysis, three or four days after infection; later the paralysis and general symptoms were followed by the death of the animals.

Kuhn and Steiner have continued their researches under great difficulties and have recently published another paper (*Zeitschr. f. Hyg. u. Infekt. Krkh.* xc, p. 417), in which they report on new successful inoculations of animals, in which they could find the spirochetes. They report their observations with all reserve and have not yet decided to claim definitely that their spirochete must be the cause of human sclerosis, which they think is not yet proved beyond all doubt, as long as the postulates of Koch have not been entirely fulfilled. They made their first observations on the spirochetes in

Strassbourg, which was founded by the Romans as a settlement under the name of Argentoratum; for that reason they gave to their spirochete the name of *Spirochæta argentinensis*.

In fact there are no very important objections which could still be made to the opinion, that the spirochete is really the causative agent of the disease. The idea that spirochetes penetrated into the blood of the animals after death may be excluded because they were seen in the blood of living animals by darkfield and in stained preparations, and likewise by silver impregnation in the liver taken from animals and fixed immediately after killing them. It is true, that spirochetes can be found in rabbits and guinea-pigs, but those that are described till now are quite different in their shape from these spirochetes. They are either non-pathogenous parasites in the blood, or they are found as cause of local spirochetal affections of the tissues, whereas the *Spirochæta argentinensis* is a pathogenic organism, living exclusively in the blood. We must agree with the authors if they say that it would be extremely curious indeed if one spirochete were found at the same time with experimental animals of two different races as causes of a fatal disease without their bearing any connection with the inoculation.

Kuhn and Steiner have made further experimental inoculations in a series of cases. Because not each inoculation can be expected to be successful, they recommended the use in every case of at least five guinea-pigs and five rabbits for the experiments. Likewise the success of inoculation will depend very much on using only quite fresh cases or cases not too much advanced, which show some acute symptoms. Even in those cases a positive result is not always sure. Of course there is some difficulty in having such cases for experimenting, as patients with those early symptoms very often do not come to the medical observation. Anyway it is useful to have early cases, especially such as show some pathological findings in the liquor.

The inoculation of animals was made by injecting blood or cerebrospinal fluid, as much as possible, into the vitreous body of the eye after discharging the aqueous humor.

In the new series of experiments researches were made on nine cases. In six cases, which were early, the inoculations were positive. Of 69 animals they used, 12 were infected, six guinea-pigs and six rabbits, showing a fatal disease with symptoms of paralysis. In one guinea-pig and in one rabbit it was possible to find spirochetes in the blood vessels of the liver by the method of silver impregnation.

From all the 13 cases which have been tested hitherto, in six old cases there were found no spirochetes; they were found in one old case with recent symptoms. From six early cases spirochetes were found in four cases.

Finally a monkey had been inoculated intraperitoneally with serum of a case of multiple sclerosis in March, 1917. In February, 1918, the monkey showed temporary symptoms of paralysis, which soon passed. In June, 1918, the symptoms of paralysis were again manifest in the lower extremities and remained so till death. The monkey did not use his legs for walking nor when he was held by the neck. When lifting up the animal his legs were flexed in the hip and knee joints. The toes were

completely paralyzed and the monkey was unable to climb. The reflexes of the inferior extremities were vivid. The monkey was killed in July, 1918. The dissection showed no pathological findings in the internal organs. In the brain there were macroscopically seen some circumscribed gray spots in the white medullar substance, of an irregular, round or oval shape, sometimes irradiating or confluent. Microscopically it could be stated that these spots were centers of degeneration of medullar sheaths. These foci of degeneration were often rich in granular cells filled with lipid substances. In the foci was seen a very intense proliferation of neuroglia cells. The axis cylinders, on the contrary, were very little affected; the resistance of the cylinders being evidently the reason for the long duration of the disease. Such degenerative foci were hitherto only found in the white medullar substance of the cerebral hemispheres, where they were disposed quite irregularly, in some places more frequent than in others. The histopathological lesions in the brain of the monkey inoculated with serum of multiple sclerosis are identical with the lesions in human cases. A detailed report on the histopathology will be published in *Zeitschrift für die gesamte Neurologie und Psychiatrie*. Spirochetes have hitherto not been found in the monkey.

From the reports published there is almost no doubt that multiple sclerosis is a well defined disease *per se* and not only a mere symptom of different other non-specific affections of the nervous system. Though perhaps at this moment we cannot yet form a definite idea of the whole pathogenesis of the disease, still it seems clear from the pathological findings that we have to deal with an inflammatory process produced by spirochetes and localized to the central nervous system, especially in the surrounding of the small venous blood vessels, which are the exclusive seat of the spirochetes. The inflammation gives origin to the proliferation of the glia cells, which is secondarily followed by degeneration of the nervous fibers. Besides the nervous parenchym also the pia mater and the connective tissue depending on it may present some signs of residuary inflammatory processes, giving thus, perhaps, some hints as to the way by which the spirochetes may have originally entered.

There is no evidence that the disease has appeared like other acute infectious diseases in epidemics or endemics, neither are there any experiences, that the disease is directly transmissible from man to man, though occasionally several members of one family can be attacked. From these facts, in my opinion, perhaps it might be concluded that we have to consider multiple sclerosis not so much as an original acute infectious disease, but rather as a late consecutive inflammatory state of spirochetal infection, which may have originated years before, perhaps without severe symptoms, but which has remained latent in the body all the time, till at least it became manifest with clinical symptoms in the central nervous system.

We know that it is a characteristic peculiarity of most spirochetal diseases, that they have an especial tendency to progress in the central nervous system, as is so well known from syphilis, relapsing fever, Weil's disease, rat-bite fever and others. The reason may be the want of sufficient anti-body

production, which must be almost a rule in all spirochetal diseases, as is proved by the frequent occurrence of incomplete cure after the first attack and of relapses in most of them, and which is also the reason that especially the nervous system is almost without any protection against the invasion of the spirochetal germs.

It is very suggestive to quote, as another example, the general paralysis, and to consider as possible that multiple sclerosis in quite the same way as paralysis is only the late manifestation of a spirochetal or leptospiral infection, which may have taken place long ago and which we do not yet exactly know in all its details. As I have mentioned, good observers have remarked the fact that clinically there is often found in the history of cases some connection with previous acute disease, generally called typhoid. Considering the form of the spirochetes it might be justified to think especially of an infection like Weil's disease, of which we know that an invasion of the central nervous system by leptospira has taken place in almost 100 per cent., as could be shown in the liquor. It would be very curious if in the liquor, in which the protective powers of the body are so little developed, such a highly virulent organism as leptospira should pass and disappear spontaneously in all the cases without settling and making any pathological lesions and consecutive symptoms in the most sensitive tissues, and, on the contrary, it would in no way be surprising, if in a certain percentage of cases at least the leptospira might keep persistent and give origin to late manifestations in the nervous system quite in the same way as *Spirochæta pallida* does in syphilis. I may mention here that also in other parenchymatous organs it could not be excluded, if not the leptospira of Weil's disease may be able to produce late anatomical lesions, as for instance cirrhotic processes in the liver, also similar to *Spirochæta pallida*. If there should be found such relations between the spirochetes of Weil's disease and chronic sclerotic processes of parenchymatous organs, we can easily understand how this fact could so long escape medical observation if we only remember how difficult it has been in such a common disease as general paralysis to discover the etiological connection with syphilis that in most countries has affected more than 10 per cent. of the whole population so that the observations could almost be made by everybody, whereas Weil's disease, on the contrary, is very infrequent and can be easily overlooked.

Also in countries where yellow fever is or has been endemic it would be very important to make researches on the question, if not the same or similar sclerotic affections of the central nervous system may be found at late sequelæ of an infection with *Leptospira icteroides*. We have known very little of diseases consequent upon yellow fever, especially of nervous sequelæ of the infection. It has not even been stated whether invasion of the liquor by spirochetes occurred, though I should consider this very probable, not only from the parallel with Weil's disease, but also from clinical and anatomical experience.

We know practically nothing at present, of how multiple sclerosis spreads, how the germs leave the sick body, how they penetrate into the newly infected body and develop and spread there. Cer-

tainly it is not probable, that the spirochetes pass the body on their way to the central nervous system without producing pathological lesions and symptoms, which may be the true source of infection. This has to be found out before it will be possible to propose any measures to prevent the spread of the disease. On the other hand, there is much hope, if the sclerosis is definitely proved to be of spirochetal origin, that the treatment will greatly profit from the fact, as it will be possible to attack the germ with spirocheticidal medicaments. It may be interesting from this point of view, that just the medical experience of the last years had brought forth the fact that in the treatment of sclerosis the injection of arsenical compounds proved superior to any other medications, which generally had given only temporary and symptomatic effects and were not able to stop the progress of the disease which hitherto seemed so hopeless in its prognosis.

PAUPERIZING THE PUBLIC.

By GEORGE L. SERVOS, M.D.

RENO, NEV.

EDITOR, "WESTERN MEDICAL TIMES."

MUCH is being said about "social medicine," "State medicine," and the caring of the health of the public by the State, without direct expense to that public. Viewed from the side-lines, we get an idea that all this is a something which will furnish jobs for a favored few and, like all things with which jobs are connected, this may be a something which may result disastrously for all concerned.

Why give medical treatment, or surgical, for that matter, to the public without direct expense to them? Why not give them their groceries, their clothing, their shoes, or furnish them with pianos or talking machines at the expense of the State? The latter would be just as logical, and perhaps all of us could live in palaces and enjoy all the luxuries of life, were they furnished us by the State.

Do those who propose the altruistic things have any idea that the public will be any better treated, medically or surgically, if the State instead of the individual pays the bills? Do they have any idea that the doctor with a job and working upon a salary paid by the State, will be a better doctor than he who receives his stipend from the individual? In so far as we have ever noticed, it has seemed to us that when one gets a public job and becomes well intrenched therein, he eventually loses his efficiency, for he does not have to use much other than his patronage to his superiors to hold that job. Efficiency usually counts for but little in connection with the holding of things of that sort.

This "State medicine," "social medicine," or whatever it may be called, is not going to be a good thing for the public, for it is going to place the whole public in the pauper class. It is going to force the individual to accept such doctor or doctors as the State may offer and he is to have no choice in the matter as to who or who shall not be his physician. It is going to make a sort of nincompoop of the man who otherwise might give a display of some sort of a working mind. A mind sufficiently well balanced to allow him to form some conclusions as to who might be the better doctor.

But being a pauper, in the eyes of the State, the individual is not going to be allowed to form any conclusions, whatsoever, but *must* accept the services of the physician assigned to his particular "panel," or whatever else the particular section of the country may be termed.

Nor is pauperizing the public going to be of any particular benefit to the medical profession. There will be no incentive to work toward a greater efficiency, for once installed in a job, and having sufficient "pull" to hold it, why should the doctor worry about a trifle like efficiency. If he be a political favorite, and these jobs will undoubtedly be political, no matter whether or not he be efficient, the job will be his as long as he may care to retain it. And the pauperized public will suffer because of such a condition, for it will not be given attention by men of true efficiency.

Anything worth having is worth paying for, and efficient medical or surgical attention is surely worth having. It is true that, under the workings of "social medicine" or "State medicine," the public really does pay for what it may get, but that is not realized at the time services are rendered by the panel doctor. Not being paid for, such services are very liable not to be appreciated—sometimes they may not be such as to be worthy of any appreciation, for they are very liable to be of rather poor quality, as are many other things meted out to the public by its servants. And one might say "servants" advisedly.

Medicine is becoming more and more of a machine, a machine under the manipulation of a favored few who happen to be in power. This machine is, without a doubt, to blame for the suggested "State medicine," or "social medicine," for such a thing will add just one more cog to that machine and make those handling it still more powerful. Even today there is but little of democracy or true Americanism in the medicine of this country. The profession, as a whole, has but little to say of its condition, and if "state medicine" comes in vogue and the people become pauperized thereby, we may expect to be further hidden under the bushel, as a whole, with but a favored few in the limelight. We will be but hidden parts of a gigantic machine and with no incentive or opportunity to allow the shining of any individual light. We may even become known by number and have to punch the time clock. For it will be of interest to the favored few, who would tell us what to do, that our identity, as individuals, be lost.

While the pauperized public may visit the doctors more frequently than would be the case were each call for such services to be paid for, still we are of the idea that that public would not be served as well as at present, for it is a well-known fact that any doctor working under contract and upon a stated salary or other income does not, as a rule, give his patients that attention usually received from physicians in private practice—physicians who must give value received, else they fail to hold their patrons. And a panel physician will be a "contract doctor" to every intent and purpose and, providing he possesses sufficient pull, the matter of giving value received will not necessarily count, to any very great extent. No matter if he be brilliant, his income will be no greater, so why

any particular brilliancy? "State medicine," to our mind, will make a lot of plodders in the medical profession—men who just get by, for what else will be needed? The breeding of Oslers, Mitchells, Mayos, Mackenzies, and men of that type will cease, for what need will there be of any such sort? Everybody will have a job and something of an income and there will be no incentive to become great, or even near-great. And anyway, paupers do not usually look for services from the great men of any profession.

We have often wondered what is the excuse for "State medicine," anyway. Primarily, it was something "made in Germany," and there it was soon found to be almost if not quite an absolute failure. A little later England took it up, and now wishes it had not. Other countries have given it a trial, with the usual results. So why America? Most Americans can pay for good medical services, and but few of them really enjoy being pauperized. Of course, as has already been said, "State medicine" will strengthen the medical machine, perhaps, but further than that we cannot see any earthly excuse for it—not in America. The real American has always been independent, both in thought and action. Let him remain so, and let him judge for himself whom he will employ as his doctor. Don't try pauperizing him if he is in position to pay for his medical services, as he does for the other necessities of life. For if you do you are going to give him the idea that the individual doctor cannot stand upon his own feet, but must have the support of the State.

A CONCEPT OF X-RAY PATHOLOGY.

IX.—FRACTURES.

BY A. J. PACINI, M.D.,

WASHINGTON, D. C.

CHIEF OF X-RAY AND LABORATORY SECTION, HOSPITAL DIVISION,
U. S. PUBLIC HEALTH SERVICE.

(Concluded.)

Fracture of the Forearm Structures.—Fracture of the olecranon process is not exceptionally common. The plane of fracture may run transversely or obliquely across the olecranon. The plane is generally straight but may occasionally be irregular. Little or no separation of fragments may be observed, or the fragments may be widely separated, the proximate fragment being pulled up by the triceps muscle. Two or three days after the fracture is obtained, the bursa over the olecranon process may become the seat of swelling, and difficulty clinically manifested in differentiating between fracture or traumatic bursitis. X-ray pathology has demonstrated that a great many olecranon injuries are really fractures without fragment separation.

Fracture of the Coronoid Process: These are considered rare, there being relatively few references to coronoid process fracture in the literature. There is a tendency in the coronoid process for the fragments to wander into the joint. The x-ray is the only sure diagnosis in these cases.

Fractures of the Head and Neck of the Radius: The x-ray has shown these fractures to be commoner than has previously been thought. Injuries to the radial head interfere with the rotation of

the forearm, making supination or flexion and extension of the elbow especially difficult. It is not impossible for the radial nerve to become involved in the callus that may form, or radial nerve injury may be sustained at the time of the primary injury.

Fractures of the Shaft and Lower End: Fracture of the lower end of the radius is perhaps the most frequent type of radial pathology. Colles' fracture ranks next in frequency to fracture of the clavicle. In a great many cases the ulna styloid is also torn off. The displacement of fragments in a fracture may assume a variety of forms. Communion is not uncommon. Impaction may be seen. The deformity may be of the so-called "fork" type, or it may assume many forms. Fractures of the shaft of the ulna may occur in a transverse or oblique plane or they may be comminuted. The tendency to displacement is not exaggerated; although frequently, owing to the pull of the pronator quadratus muscle, the lower fragment may be drawn over toward the radius. The fracture frequently accomplishes dislocations of the head of the radius and is not recognized because of the more severe injury; so that in fractures of the ulna or in dislocations of the radial head an x-ray should be taken of both regions, the ulna fracture being scrutinized for the possibility of a complicating radial head dislocation, and vice versa, radial head dislocation should be scrutinized for the possibility of ulna fracture. Precise diagnosis is imperative for guiding in the treatment. The radial nerve is sometimes involved in fractures of the ulna shaft.

Barton's fracture consists in the breaking off of the posterior tip of the articular end of the radius at the wrist. For purposes of x-ray pathology, a fracture at the wrist that is completely transverse, the line of fracture not being directed toward the wrist joint, may be called a Colles's fracture; whereas, a fracture whose direction is not transverse, the line beginning at the side of the bone and curving, meets the joint space, may be described as a Barton's fracture. Barton's fracture must clinically be differentiated from injuries of the scaphoid and semilunar bones. The differentiation is effected by means of the x-ray.

Fractures of the Shaft of the Radius: In this, the fracture may assume many planes; but it is commonly transverse or oblique and is rarely comminuted. Displacements vary from those of a transverse fracture, where there may be little more than an angular change in the axis of the radius at the site of the fracture, the bone ends holding opposition; or, in transverse fractures with displacement, or oblique or comminuted fracture, angularity forward and inward with a moderate degree of overriding. It should be remembered that rotation may occur between the two fragments with very little evidence of angularity in the x-ray. This is especially true in those fractures that occur above the insertion of the pronator teres when the biceps tends to supinate the upper fragment and draw it forward. Fracture of the middle third, or just above the attachment of the pronator quadratus, may be followed by pulling of the upper fragment into outward rotation and abduction, the pronator quadratus muscle at the same time drawing the

upper ends of the lower fragment toward the ulna. Careful x-ray examination and diagnostic interpretation should be conducted in the case of fractures of the radius and ulna for the reason that, while these fractures are not dangerous to life, they are the most dangerous as regards loss of function. It seems to be generally decided that the best means for the treatment of these fractures is that with the hand in full supination; and the x-ray guide should frequently be used to make certain that callus proliferation should in no way interfere with the desired end.

Fractures of the Carpal Bones.—The navicular bone, or carpal scaphoid, is an important structure for the x-ray pathologist by reason of the fact that the controversy, championed primarily by Dwight, as to whether or not a bone is fractured or congenitally bipartite, still arises in visualizing traumatic pathology involving this structure. The question of bone variations leading to the "law of multiple variations" has already been discussed. According to Dwight, the scaphoid consists essentially of two parts, the radial and an ulnar part, and sometimes may present certain accessory ones, namely, an external and central radial bone. It would seem that if the opposing surfaces of a bipartite scaphoid are roughened, that the lesion presents primarily a fracture; at least, this is the contention advanced in those textbooks discussing the problem; but, as Dwight shows, the scaphoid, by reason of its anatomical position and function in the wrist, is so located as to make for maximum friction between the two surfaces of a dividing bone. So that even congenital subdivision of the navicular might well be accompanied by roughened approximating surfaces. A method for the determination of whether a bone is congenitally bipartite or traumatically fractured is that of photographically enlarging an x-ray picture of the divided bone according to the method outlined for the teeth under the discussion of odontopathy. The purpose of the enlargement is to show the trabecular orientation. If the orientation is differently planned in both sections of the divided bone, the x-ray inference would be that the bone had arisen from separate centers of ossification and is therefore congenitally subdivided; but if the orientation tends to continuity and is ruptured by the line of fracture, the inference would be that the subdivision results from trauma rather than from a congenital cause. When the navicular is fractured other than in its center, at right angles to the long axis, a diagnosis of fracture is usually more readily made. X-ray examination is important in trauma, sustained in the region of the wrist to differentiate a Barton's fracture from a fracture of the scaphoid.

Fracture of the semilunar is difficult to distinguish by any evidence other than x-ray. Congenital division of the semilunar does occur, when it is divided into a ventral and dorsal half; but since these halves are superimposed in a postero-anterior view of the wrist, the x-ray pathology is not confusing on this score. Fractures of the remaining carpi are not common, and if they occur may readily be diagnosed.

Fractures of the metacarpal bones are common and generally present little difficulty in their recognition.

Fractures of the phalanges are also readily recognized.

Fractures of the Femur.—Fractures of the head of the femur, relatively uncommon, are sometimes difficult to recognize by reason of their smallness and further by reason of the fact that generally they are crush fractures, the separated fragments remaining impacted in the head of the femur. Careful x-ray examination will reveal their presence.

Fractures of the neck of the femur may involve any part, but generally are to be found either near the head or near the trochanters at the base. If the separation is complete, and the fracture is near the head, the angle of the axis of the head is changed relative to its position on the femoral shaft, and is directed upward and forward. These fractures have been classed as intracapsular. Fractures at the base of the neck into the trochanter are classed as extracapsular. The displacement of the head in extracapsular fractures is similar to that occasioned in intracapsular fractures, but is generally more marked in both planes of displacement, upward and forward; and since treatment consists in aligning the remaining femoral shaft in the axis of the head, in order to obtain muscle rest, it is important that careful x-ray control be given in obtaining extreme abduction and inclined plane.

Fractures of the shaft of the femur may be of all types, the pathology depending upon the part of the shaft involved, upon the normal curve of the bone and upon the muscle balance at the point of fracture. In the middle third it is common to find a transverse fracture; whereas, in the upper third extreme obliquity is the rule. Displacement is greater than in fracture of any other bone owing to the tremendously powerful muscles concerned. In transverse fractures, where separation is complete, overriding manifests practically at once, the lower fragment being drawn upward and behind the upper one and the angularity existing is directed outward and forward. The lower fragment generally rotates outward, being turned by the weight of the foot and leg. In fractures of the upper third, the proximal part is pulled forward and outward by the muscles attached at the trochanters, the glutei and psoas, while the flexors and adductors draw the lower fragment inward and up against the upper fragment.

The knee joint, in cases of shaft fracture of the femur, sometimes develops signs conducive to investigation. There may be an effusion into the joint and later, in many more than half of all cases, a tendency to stiffness is to be observed. While a chronic periarthritic change involves the knee joint, it is difficult definitely to elicit any x-ray pathology.

Supra- and Inter-condyloid Fractures: These are generally associated, the plane of fracture being transverse or oblique and at any height above the condyle. When oblique from behind downward and forward, separation may be great, the upper fragment being driven down toward the knee, the lower fragment riding upward and downward owing to the pull of the gastrocnemius.

Condyle and Epicondyle: Either condyle may separate, the size of the fragment detached being more or less small or large, depending upon the bulk of the condyle separated. The displacement is usu-

ally backward and upward, or it may be lateral and upward. The lateral ligaments retain their hold above unless they are ruptured. The crucial ligaments may be injured at the same time. In lateral displacements, the knee appears wider. There is always effusion of blood into the joint cavity, sometimes to the point where fracture is not suspected at all, until the x-ray examination is made, or until the knee swelling has subsided and a more careful clinical examination can be conducted.

Fractures of the Patella.—Transverse or oblique fractures occur most frequently. The line of fracture may be straight or it may be step-like or curved. In longitudinal fractures complete separation of the fragments is not the rule; but should complete separation be found, one fragment is usually laterally dislocated outwardly, owing to the pull by the vastus externus insertion. The amount of displacement of fragments is dependent entirely upon the degree of concomitant fracture of the fibrous aponeurotic investment of the bone, the drawing of the lateral ligaments, and the synovial membrane of the knee joint. It should be remembered that the patella is the one bone of the body subject to refracture more often than any other sesamoid.

Fractures of the Tibia and Fibula.—The head of the tibia presents the articular surfaces turned slightly upward and separated by the two tubercles of the tibial spine. Between the two tubercles is a groove which continues in both directions and broadens into the intercondylar fossa. In the wider and anterior fossa are attached the anterior crucial ligaments and the anterior edges of the lunate cartilages; whereas, in the posterior fossa, which inclines down and backward, the cartilages are attached to their respective sides of the spine and the posterior crucial ligament is joined to the rounded surface posteriorly. X-ray pathology in ruptures of the crucial ligament is unsatisfactory. The pathology of semilunar cartilages has elsewhere been discussed.

The anterior tubercle may partly or completely separate; a condition called Schlatter's disease. The condition cannot occur after the age of seventeen. Separation after ossification is more extensive, involves a larger fragment of bone and is accompanied by greater displacement.

Fractures of the upper end of the tibia alone, or of the tibia and fibula together, may sometimes present severe comminution or the line of fracture may assume a most varied direction. Transverse fractures are exceptional; oblique are common and involve usually the knee joint or separate one tuberosity from the head. When the displacement is minimum, impaction is the rule. In fractures of this region the popliteal vessels and tibial arteries are subject to dangerous injury. The joint invariably suffers an effusion or hemorrhage. The swelling incident to the effusion is a marked characteristic and may attain such proportion as to obscure the clinical identity of a fracture, which may be mistaken for dislocation.

Separation of the upper epiphysis is uncommon owing, says Hutchinson, to the strong ligament and tendon protection acting as powerful retainers of the epiphysis to the shaft.

Fractures of the shaft tend to run toward the

concave side of the tibial flexion. In children, fracture of the tibial shaft alone is more common than in adults, when the tibial and fibula shafts are usually conjointly fractured. It is in this bone that spiral fractures are particularly common. External rotation of the mobile peripheral part of the leg is more common than internal rotation, so that spiral fractures of the right leg are left handed; and, contrariwise, spiral fractures of the left leg are right handed. To this rule there are exceptions. Shaft fractures may assure all varieties of displacements. As a rule, excess callus is rare in the healing of leg fractures.

The lower epiphysis separates more often than the upper. In the separation of epiphysis, the danger to thwart growth is great; but while this is of clinical importance, it is beyond control of the roentgenologist.

Pott's fracture is quickly recognized by its x-ray pathology and offers little comment. Fractures of the fibula alone are rare unless at the lower end.

Fractures of the tarsals are not uncommon, the calcaneus being most frequently affected. There may be compression fractures of any of the bones. Variations of the tarsal bones should always be held in mind, particularly the os trigonum and the divided pedal scaphoid. The os trigonum is the external posterior process of the astragalus. Very rarely this separate bone may be found divided.

A most interesting variation in the pedal scaphoid is that described by Pacini. It was found twice at dissection, once in the collection of plates examined at the Army Medical Museum (easily 10,000 ankles) and again in a marine who chanced for dispensary treatment and x-ray observation during the course of writing these articles.

The pedal scaphoid varies greatly in its size and in its shape. Its tuberosity may not be identical with the tibiale externum. The tibiale externum is commonly designated a sesmoid in the tendon of the tibialis posticus, but Dwight insists that it is a true part of the skeleton. It is to be observed that all the variations in additional bones involving the pedal scaphoid are described as affecting the scaphoid on its anterior convex surface between the internal and middle cuneiforms. Sections of tibial scaphoids have, in 8 per cent. of two hundred and fifty cases, indicated the possibility of an additional center, involving the posterior surface of the scaphoid at the facet articulating with the astragalus. In the four cases above described a triangular wedge was distinguished isolated at the posterior superior portion. This separate bone may be mistaken for fracture. It is placed in a position where it receives much friction so that the frayed edges of the bone, while they would suggest a traumatic separation, are really the result of prolonged irritation, incident to the mechanical imperfection of a divided tibial scaphoid. In one of the cases studied by x-ray control, the tibial scaphoid remained frayed in its contour for seven years.

CONFUSING ARTEFACTS.—There are radiopacities and radioparities that appear in the normal plate that may make for error in interpretation. Partly to avoid this it is a wise expedient always to ray the corresponding part for comparison in any given roentgenological study. Linear striations are threefold. The first are those incident to epiphyseal

lines, appearing as definite breaks in the continuity of the bone. The x-rayist should ever be on the guard against such misinterpretation by familiarizing himself with the table of epiphyseal ossification. If a muscle bundle crosses a bone there may be a sharp black line possibly confused for a fracture. This mistake has been made in the case of a transverse process of the lumbar vertebra crossed by the superimposed belly of the psoas muscle, giving an appearance that simulated a fracture through the transverse process. Another possibility of error is that in mistaking the course of a blood vessel in the skull for fracture line. Familiarity with the internal and x-ray anatomy of the skull will make for elimination of this error.

The roughening of bone edges, particularly in the region of the attachment of tendons, is sometimes erroneously diagnosed periostitis. The roughening should be reported with the cautious advice that its location is such as to preclude the possibility of great pathological significance. Intestine which is meteoric and superimposed on a bone, particularly the ilium, may render the underlying bone structure so radioparent as to give the appearance of a perforated osteomyelitis. This error is rare but it has nevertheless occurred. Warts and fibromata, metallic salts, and defective plates may be other sources of confusion.

Medicolegal Notes.

Jury's Finding as to Method of Treatment Not Decisive.—In an action against a surgeon for malpractice in the alleged improper treatment of a hernia the evidence showed that the defendant used an injection method. Several doctors of unquestioned repute and experience testified that this method is obsolete, that it was not a proper treatment and that the plaintiff's injuries were due to its administration. Several doctors for the defendant testified that the treatment was a recognized or proper one, but not much used at present. Under such state of the evidence it was held a jury question whether the defendant was negligent in the plaintiff's treatment. A finding by the jury that the method used was proper or improper did not decide defendant did not use a method ordinarily used by surgeons of good standing, without a finding whether the any issuable fact.—*Stenkowiczki v. Lytle*, Wisconsin Supreme Court, 177 N. W. 848.

Expert Testimony as to Proper Method of Treating Drug Addicts Admissible.—During the progress of a trial of a duly registered physician for violation of the Harrison Anti-Narcotic Act, the government tendered as witnesses three physicians of the district to testify as experts as to the proper method recognized by the medical profession for the treatment of narcotic addicts. The defendant objected to such expert testimony on the ground that expert testimony was inadmissible, and that the facts only as to what the defendant did in the practice of his profession in the treatment of addicts under the indictment were admissible. The defendant was charged with illegally dispensing the drugs; his claim was that the drugs were dispensed in the course of his practice as a physician. The Circuit Court of Appeals, Fifth Circuit, held that it was material and proper for the jury to be informed of the method recognized by the medical profession for the treatment of drug addicts, and this method could only have been detailed by men skilled in medicine; otherwise, any physician could dispense the forbidden drugs in any quantity to persons not his patients, and thus defeat the purposes of the act. The issue being whether the drug was dispensed in the legitimate course of the defendant's practice as a physician, the evidence was held admissible on that issue.—*Reeves v. United States*, 263 Fed. 690.

DEFENCE AGAINST ADVERSE LEGISLATION.

WE live in strenuous times and it is as true now of the medical profession as of the nation that its liberty can be preserved only at the cost of eternal vigilance. In the good old days of a former generation physicians had few harassments apart from their professional duties and were able to devote themselves to the care of their patients without lay molestation. Those who longed for a ruction had to get up a dispute among themselves over the code of ethics or some other academic subject, for the State respected medicine and left its votaries to rule themselves. But one evil day some restless and altruistic spirits among us conceived the idea that the public needed protection from irregular practitioners. The public was doing very well and as a rule those who really needed medical care had nought enough to distinguish the true physician from the faddist and the quack, and everybody was content. But these medical reformers would not have it so, and to protect those who were in no need of protection they persuaded the legislators to pass medical license laws. Then the trouble began. The politicians awoke, or were awakened, to the fact that here was virgin soil to work—and they worked it. Turn about was fair play, and if the doctors were so eager to interfere with the liberty of the public to choose its own healers, the public might become interested in limiting the amount of liberty the doctors should be permitted to enjoy. So the law makers got busy and first stretched out a sheltering arm over all sorts of healers who formerly had to work in the dark or who suffered from the reproach of irregularity; laws were passed raising them to an equality with medically educated practitioners, formerly esteemed as the only real physicians. Then having tasted blood, the legislators passed law after law regulating medical practice and prescribing a maximum dosage of various drugs, and appointed hirelings, lay and medical, male and female, to see that these laws were executed in a way best adapted to inconvenience and irritate the honest practitioner.

Formerly the harassed doctor looked to his county and State societies to protect him against ad-

verse legislation, but now to his dismay he not infrequently finds his natural protectors failing to oppose, if not actually supporting, one objectionable bill after another. As a matter of fact the county and State societies are not the proper agencies for safeguarding the material interests of the medical profession. They were founded primarily to provide an arena where scientific questions could be discussed. Now science and politics do not mix well, and a realization of this fact has led to the organization of societies having as their main object the prevention of legislation inimical to the medical and allied professions. One of these societies, a pioneer in the work and a type of the class, is The Professional Guild of Kings and Queens Counties, New York, membership in which is made up of physicians, dentists, and pharmacists. This Guild has the usual officers, a board of directors and an executive secretary whose whole time is given to the service of the society.

A brief summary of the recent work of this organization may be of interest as showing in what its activities consist. The Guild proposed the bill introduced by Assemblyman Lord, mention of which was made recently in our news column, the object of which is to repeal the State narcotic law and abolish the narcotic commission. Soon after this bill was introduced the Guild arranged for a mass meeting in Brooklyn in opposition to the new regulations suggested by the narcotic commissioner. At this meeting representatives from numerous scientific societies in Greater New York spoke, and, in a spirit of fairness first Deputy Commissioner Mulhall was invited to make the first speech. She accepted the invitation and embraced the opportunity to state that, although her statistics showed that only five per cent. of physicians, dentists, and pharmacists were crooked, she believed 20 per cent. were. A committee was then sent to Albany to meet the narcotic commissioner and arrange for a hearing in New York City in opposition to his regulations. Later the Guild took an active part in securing a large delegation from medical societies throughout the State for the hearing at Albany on the various narcotic bills. At this hearing 98 per cent. of those who spoke favored the Lord bill. While on the train returning from Albany the delegation was informed by the lady deputy commissioner that the new regulations would be pushed to the limit. Therefore another mass meeting of representatives from the various societies was called at which it was determined to enjoin the commissioner from enforcing his regulations (papers have since been served on him) and to use every effort to secure the passage of the Lord bill and to abolish the superfluous State narcotic commission.

This is only a small part of what this one society has done, but it proves the value of a non-scientific organization of the kind to do work which the individual doctor could not possibly do alone and which the county or State society could not do as effectually without neglect of its scientific interests.

When one thinks of all the measures under way or threatening—compulsory insurance, annual registration, health centers, chiropractic licensure, antivivisection, and others nearly as vicious, it is easy to see that only a strong organization, having a single aim, can save us from the assaults which our altruism of many years back laid the profession open to, if it did not actually invite them.

THE BABY'S MILK.

Of equal importance with the much-discussed subject of milk-modification is the less-discussed subject of the kind of milk to modify. On some points there seems to be a fair degree of unanimity. Very few advocate the prolonged feeding of any canned food to babies. Practically all pediatricians use cows' milk in some form in the routine artificial feeding of infants. The question at issue, then, and it is a question which merits clarification, is whether the infant should be fed raw certified milk, pasteurized milk, or boiled milk. Certainly if raw milk be used, the ordinary "market milk," with its higher bacterial content and greater likelihood of causing trouble, should be avoided. The champions of raw milk should be the champions of certified milk. They should also be interested in seeing to it that certified milk is all that it is certified to be.

Those familiar with bacterial counts for the past year know too well how frequently certified milk has failed to meet the requirements of the various medical milk commissions. At the meeting of the American Association of Medical Milk Commissions, held in Louisville in November, 1920, it was fairly agreed that the "labor situation," more than any other factor was, and is, responsible for the frequently high bacterial content of certified milk. The occupation of dairyman stands competition with other trades very badly—due partly to irregular hours, partly to the general aversion to any sort of farm work, largely to the higher wages paid to industrial workers. Employees in a certified dairy must be intelligent, careful, teachable; they must take what would seem to the ignorant and indifferent, ridiculous care in their work. Such workers have been difficult, often almost impossible to get. Producers, usually far less able than distributors to weather any storm, have often been obliged to make use of milking machines to make the available labor accomplish more. Milking machines are notoriously hard to clean. They may effect a reduction in the number of laborers employed; but they require the most intelligent and painstaking care in their use, if the bacterial counts are to be kept within certification requirements. Clearly, those who favor the use of raw certified milk in infant feeding have to contend with the fact that bacterial counts are occasionally, in some communities frequently, high; and that a few virulent streptococci, even though the actual count be well within requirements, can do serious damage to infants.

If the milk is properly cared for afterward, pasteurization makes it safe for use by adults and

young children. Though the bacterial counts of pasteurized milk are often high, the likelihood of pathogenic organisms being present is very slight.

The complete safety and ready digestibility of boiled milk are certainly powerful arguments in its favor as the best form of milk to use in infant-feeding (provided of course that care is taken to furnish antiscorbutic vitamins). If we boil the milk, the necessity for using the more expensive certified milk is at least questionable—especially as the fat content of market milk is not likely to fall below standard. It requires an enormous amount of effort on the part of medical milk commissions, producers, and distributors, to keep bacterial counts below ten or even fifty thousand. The corresponding increase in price of such milk practically prohibits its use by the poor. The infant mortality-rate has always been a check (albeit an immorally expensive one) on the purity of the milk supply. Will boiling the infants' milk allow producers to "get away with" grossly contaminated milk? Decidedly, it should not. There are no accurate data on how many killed bacteria can be fed with safety. And no one would relish having the point decided by his own baby.

Most of those who favor boiled milk for infants agree that milk need not be boiled after the baby has reached the age of two years. Should not young children above two years of age be given raw certified milk? Such children are in all probability, or at any rate should be, taking a fairly general diet. It is inconceivable that pasteurized milk should be harmful to them. In fact it is becoming increasingly clear that the entire milk supply should be pasteurized. It is safe to say that if the efforts at present being expended by the profession on certified milk were to be devoted to securing a supply of pasteurized milk of acceptable purity—say a fat percentage of 3.5 and a bacterial count not to exceed 250,000—the result would be distinctly beneficial. At any rate it would be far better than the condition at present prevailing in many communities: a badly contaminated milk supply for the general public and a hyper-pure milk supply for the relatively few who can afford its higher price.

DIRECT PATERNAL ANCESTRY OF GENIUS.

Of recent years, perhaps in part due to the gallantry of feminists, the claim has been reiterated that prominent men derive their talents chiefly from the mother, the influence of the father being almost negligible. As far as we know there has never been any scientific statistical basis for such a claim. On the contrary, Galton years ago proved conclusively that many men of great talents and achievement were sons, grandsons, or nephews of prominent men bearing the same name. Despite the great resemblance of many men to their mothers and maternal grandfathers, family portraits extending over many generations often show remarkable "throwbacks" to paternal grandfathers, great uncles, etc. We have seen the statement that

hereditary characteristics tend to die out after four or five generations, but it is difficult to understand how this could happen, because the ancestor "thrown back to" should in turn "throw back" to some ancestor of his own; possibly the chances are against throwing back on the paternal side, for after all this may be the exception.

Those who believe strongly in the influence of the paternal line are inclined to disbelieve in the obscure paternal ancestry of talented men. Granted that the father and grandfather were obscure, it is possible that back of the latter there was recognized ability. Biographers of men of humble origin often make strenuous efforts to connect their subjects with distinguished namesakes, and usually without much success. Yet occasionally it happens that a presumption of this ancestral superiority comes to light through the results of trained genealogical effort.

It has generally been believed that Burns the poet was of thoroughly plebeian origin. The poet himself inclined to this view, for a careful search through books on surnames and heraldry revealed no trace of his own, which was really Burness, a name evidently not the same as the familiar surname of Burns. Several years ago the discovery is said to have been made that a presumable ancestor of Burns in the paternal line with the born name of Campbell and of some prominence, had for certain reasons changed it to Burness. The evidence is said to have been imperfect enough to cause the truth of the statement to be challenged and the question must be left open. In the case of Poe the evidence that his family name was originally Powell is strong if not conclusive. Bewley, a professed genealogist, collected the data and published them in 1907, but the fact does not seem to be generally known. The Poes of the County Cavan in Ireland, the poet's forbears, disappear from the records about the middle of the XVIIIth century, as if lost in complete obscurity; but Bewley had little difficulty in connecting them with the Powell family of that region, in which they had been well known for several centuries. There is absolutely no evidence to connect this branch of the Poes, at least, with the Poer or Power families. Of course the paternal grandfather of the poet, General Poe, was a man of eminence, but it is of some interest to trace the right male line to prominent folk in the old country.

Doubtless attempts of the same nature would repay the effort in the case of other men of talent. According to one pedigree Edwin Booth was a lineal descendant of Barton Booth, a great actor in the XVIIth century. His paternal grandfather, however, is said by some biographers to have been of Hebrew extraction, and in such a case the name of Booth must have been assumed. In this connection it may be said that Bret Harte was fully aware that his paternal greatgrandfather was Abraham Hart, the Hebrew founder of the New York Chamber of Commerce, and that his surname was not related to the familiar British name of Hart.

THE TREATMENT OF PULMONARY EMPHYSEMA.

THE treatment of pulmonary emphysema may very rightly be regarded as the type of palliative treatment in which, on account of sheer inability, we are obliged to deal with a lesion which becomes definitively confirmed. But the distressing accidents to which the patient is the prey or those which threaten him can be cared for.

This treatment is largely hygienic and is based upon the fact that the patient must abstain from all activity and ceaselessly care for his daily existence. For those who are able to carry out this manner of living and can change climates according to the season, in order to enjoy continually a dry atmosphere and an almost equal temperature, the pulmonary condition may be kept in check and the patient fairly comfortable. The emphysematous subject is fragile and should be regarded as such, otherwise an aggravation of the pulmonary lesion will arise and the risk of cardiac complications will be considerable and constitute the great danger to the patient.

For some observers the diet should be rigorously regulated, all meat being practically excluded, at least for a certain time, while an exclusive milk diet is enjoined during difficult phases of the affection. Others are less strict in their prescriptions, although they advise great care in diet in order to avoid an overplus of food and especially auto-intoxication from the digestive tract, which may be the starting point of acute paroxysms and other complications. Constipation should also be persistently treated.

Treatment, properly speaking, comprises physical and medicamentous therapeutics. The former may be summed up in aerotherapy, which can be carried out by baths of compressed air, or by pneumotherapy, which is a variety of the former and undoubtedly less subject to caution. As treatment which cannot profitably be employed other than in large establishments, aerotherapy also requires very strict medical oversight. Unquestionably, it has given very appreciable results, but in many cases it has been found necessary to give it up. Cases which benefit by it must be selected with extreme care and, as Robin very justly remarks, patients with high blood pressure, arteriosclerosis, cardiopathies, pulmonary tuberculosis, obesity or plethora should abstain. The same observer recommends hydrotherapy in the form of the Scotch douche as a regulator of the nutrition, accelerating diuresis and, in a fashion, brings about a cutaneous reaction which diminishes the tendency to bronchitis, all ways to be feared in these subjects.

Treatment by drugs is limited and about all that can be essayed are iodine as a basis, strychnine often useful as a tonic, morphine and its succedaneous products for the dyspnea, and balsams, such as terpin, for eliminating bronchial mucus. Iodine is not a remedy for emergency use in emphysema, but rather an agent to be exhibited con-

tinuously. Therefore, the daily use of potassium iodide must be resorted to, and when administered for a prolonged period it improves the permanent dyspnea and frees the bronchi from adherent mucus which otherwise fills them.

PSYCHOLOGY OF THE TUBERCULOUS.

SEVERAL well known phthisiologists have taught that the tuberculous subject tends to be self-centered and indifferent to the comfort and welfare of others, while Dr. Knopf of New York has expressed his disbelief in this teaching, perhaps regarding the consumptive as as much of an altruist as a patient with any other chronic incurable disease. In a paper on the psychology of the chronic invalid Ichok (*Journal de médecine de Paris* for January 10, 1921, xl, 1) touches incidentally on the psyche of the consumptive. He quotes a page from Daremberg, a famous phthisiologist, on the latter subject, but thinks it would apply with equal force to the sufferer from any other chronic malady. Daremberg attributes strong egoism to the consumptive and narrates a number of its expressions, one being that the victim of this disease cheerfully allows his friends and relatives to wear themselves out in his service and is utterly indifferent to the possibility of communicating his disease to others. Laignel-Lavastine, the well known alienist, speaks of this egoism as negative rather than positive. Realizing his weakness and helplessness the consumptive accepts attentions as might for the same reason a child. But he does not exhibit an active, aggressive egoism. Ichok barely mentions the characteristic optimism of the consumptive: for if the latter believes that he is getting better—as he is very apt to do—such belief must react on the psyche, and hence perhaps the subject of the *spes phthisica* merely feels that he can make up the sacrifices of his relatives after his recovery. Many adolescents impose on their parents and companions from the same motive—they expect to prosper amazingly in life and then it will be a mere bagatelle to repay favors. The author mentions the surprising sexual potency of many consumptives—amounting at times to an erotomania—and believes that the phenomenon may be in part responsible for the optimistic tendency, since a man who is sexually strong cannot well visualize himself as doomed to death.

SPORTSMEN'S EPICONDYLITIS.

AT a meeting of the Lyons Surgical Society on January 20, 1921, Tavernier read a paper on this affection which, while very common, is but little known to the profession (*La Presse Médicale*, January 29, 1921). He reported two cases, the duration of which had been three and seven years respectively. It was probable that the lesion was an osteoperiostitis of the epicondyle at the area of insertion of the muscles, due to overstrain. The x-ray showed a proliferation of the periosteum. The affection might readily be confounded with sprain, rupture of muscle, or an osseous deformity, and doubtless usually passes for one of these conditions. The seat of the pain is said to be just above and in front of the prominence of the epicondyle. Swelling or hematoma has not been seen. It is not improbable that a minute splinter of bone has been torn away in some of the cases as a result

of sudden muscular contraction. Villard has located the pain at the insertion of the extensor communis and has found the condition obstinate and progressive. When the patient rests there is a remission and when he begins to exercise it returns. Both Villard and Tavernier mention the loose cellular tissue which lies beneath the tendons of the extensor muscles, separating them from the insertion of the supinator brevis. It is possible that exceptionally a bursa forms in this area and its inflammation is at the root of the trouble in these cases.

News of the Week.

Quarantine for Emigrants at Cherbourg.—From twelve to fifteen days' quarantine for emigrants bound for the United States in the steerage will be required at Cherbourg, France. The steamship companies are preparing inspection, disinfection, and housing facilities for an average of three hundred emigrants at each sailing.

France's Youths Unfit for Army Service.—According to reports by medical boards who have been examining the class of 1921, which will join the colors next month, of more than 300,000 eligibles only 165,000 measured up to the ordinary physical standards. Doctors recommend the passage immediately of a law making physical education compulsory in all French schools.

Smallpox Epidemics.—Albion College, Albion, Mich., has been closed and all the students sent to their homes until April 5 because of an outbreak of smallpox in the institution. In Collinsville, Oklahoma, 100 cases of smallpox have been reported to the city health officer within a short period. West New York, a district adjoining Union Hill, N. J., has been placed under quarantine by the New Jersey State Board of Health following the discovery of seven cases of smallpox. The schools and places of amusement in West New York have been closed.

Eugenics Bill Defeated.—A eugenics measure, requiring applicants for marriage licenses to file physicians' certificates stating their mental and physical qualifications, was defeated by the Michigan Senate on March 17.

Chicago Cuts Death Rate.—The death rate in Chicago, during February, 1921, was nearly 50 per cent. lower than during February, 1920, the average death rate being 13 per 1000 population. There was a marked decrease in the communicable diseases reported, there being 7,767 for February of this year against 15,712 for February, 1920.

Danger Signal for Whooping Cough Victims.—The Board of Health of Lansdowne, Pa., requires that every sufferer from whooping cough, whether adult or child, shall wear a red flannel band four inches wide around the left arm. A child so tagged may travel the streets, provided he is accompanied by an adult, but will not be permitted to attend a public gathering or enter a store. Should the privilege be abused quarantine will be imposed.

Course for Medical Officers.—Plans are being made by the officers in charge of the Medical Field Service School of the United States Army, located on the site of the old Indian school at Carlisle, Pa., for the accommodation and training of large num-

bers of commissioned and non-commissioned officers of the United States Army who have chosen to serve in the medical branch of the Army. Approximately seventy regular class medical officers will be sent to the Carlisle School on June 1 for a short course for medical corps officers. This school is part of the program outlined by the War Department for the education of medical officers for capable service either in time of war or during peace times. The men who will be sent to the school in June are now in training at the Army Medical School in Washington. The training is also to be extended to dentists and veterinarians.

State Guard Medical Unit Mustered Out.—The local medical unit of the Connecticut State Guard was mustered out of service at the State armory on March 10. Major C. C. Gildersleeve, now in the State guard reserve, formerly commanded the unit.

New Kansas City Hospital Opened.—The Physicians and Surgeons Hospital, an open staff hospital, has recently been established in Kansas City, in a building which was formerly the East Hotel, at Eleventh and Harrison Streets.

Plan to Extend Work of Chicago Hospital.—A campaign to raise \$500,000 for the extension of the Illinois General Hospital and Cancer Research Foundation will be begun on June 1 and continued for ten days. It is expected that fully one-third of the work of the hospital will be free clinical and dispensary work. Dr. E. S. Pettijohn is chairman of the campaign fund.

Van Cortland Hospital Reopened.—Van Cortland Hospital, the annex to Montefiore Home, New York, which was operated by the Government for the care of wounded officers, has been reopened as a rest home for paying patients.

Ask Pardon for Doctor.—The first application for pardon of a physician for violation of the State drug Act in Pennsylvania, so that the way may be clear for him to appeal for restoration of license to practice, has been filed with the State Board of Pardons. The State Bureau of Medical Education and Licensure, which has charge of the enforcement of the drug act in Pennsylvania, has revoked the license of a number of physicians.

Brooklyn Surgeon Sued for Damages.—An action for \$50,000 was begun in the Supreme Court, Brooklyn, on March 19, against a surgeon who is accused by a woman patient of having sewed up a needle in her abdomen following an operation. A second operation was performed, but no needle was found, and no relief resulted. The defendant has made a general denial and has applied for a bill of particulars.

New Courses in Psychological Medicine.—The craze for psychoanalysis and its practice by the unqualified is being counteracted in England by the establishment of courses in psychological medicine in British universities. Last year a course of lectures was instituted by Cambridge University under the direction of Sir Frederick Mott in order to qualify students for a diploma in psychological medicine. More recently London University, the Royal College of Physicians and Surgeons, and the Universities of Leeds and Edinburgh have provided similar courses, which lead to a diploma in this branch of medicine.

Typhus Fever Death in Youngstown.—Advises

received at the New York City Health Department report that a case of typhus fever has appeared in Youngstown, Ohio. The victim arrived in this country on the steamship *Ryndam*, on February 6 and came down with typhus fever on March 7, twenty-two days after his arrival.

Red Cross Robbed in Warsaw.—On the night of March 13 burglars blew open an old Russian safe in the American Red Cross quarters in Warsaw and abstracted 925,000 Polish marks, belonging to the American Red Cross. Of this sum 772,000 belonged to American doctors and nurses.

Influenza Again Appears.—A widespread epidemic of influenza in which nervous symptoms seem to predominate is reported from London. An increase in the number of cases reported in New York City is also noted since March 1. The records of the New York Health Department show that there have been 1,038 cases and 120 deaths from the disease reported since January 1.

Antianthrax Serum Available.—The Bureau of Laboratories of the Department of Health of New York City announces that it has on hand a limited supply of anthrax serum which will be furnished to physicians for cases under their care in New York City, and who are actually unable to buy the commercial product. The serum is the gift of a commercial concern none having, as yet, been prepared by the Department of Health.

Dr. Joseph Marshall Flint has resigned his position as professor of surgery in the Yale Medical school, on account of ill health. His resignation is to take effect in June.

Dr. Charles Ballard of Flint, Mich., a reserve officer in the United States Public Health Service, has been ordered to active duty in the Public Health Hospital at New Haven, Conn.

Dr. H. S. Newcomer of Philadelphia has resigned from the Pennsylvania Hospital for Nervous and Mental Diseases in order to accept a position at the Henry Phipps Institute.

Dr. Thomas R. Donovan of Fitchburg, Mass., has been appointed by the United States Public Health Service to be district medical examiner for the Fitchburg district.

Dr. H. D. Bernard of Sacramento, Cal., has resigned his position as city physician.

Dr. Eric A. Crull has resigned as city Health Commissioner of Fort Wayne, Ind. Dr. Maurice Lohman will succeed Dr. Crull as Health Commissioner.

Miss Winifred Holt of New York, founder of the Lighthouse, an educational institution for the blind, has been decorated in behalf of King Emmanuel of Italy in recognition of her services to the blind of Italy during the world war.

Dr. Charles F. Painter has resigned as dean of Tufts Medical School. He will continue, however, as a member of the faculty, retaining his title of professor of orthopedic surgery.

Major C. P. Faller has resigned as regimental surgeon of the Eighth Infantry, Pennsylvania National Guard.

Dr. William Sharpley has been elected president of the State Board of Health of Colorado.

Dr. B. R. Leroy has been elected health officer of Trumbull County, Ohio.

Creighton Alumni of '96 Have Reunion.—The

second graduating class of Creighton Medical College, which went out from the college in 1896, held a reunion on March 3, which was attended by five of the original twenty-one members of the class. Dr. D. J. Hammond of Omaha was president of the class.

Harvey Society Lecture.—The ninth of the present course of Harvey Society Lectures will be delivered by Dr. F. Gowland Hopkins, Professor of Biochemistry at Cambridge University, at the New York Academy of Medicine, on the evening of April 2. His subject will be "The Chemical Dynamics of Muscle." The following Harvey Society lecture will be delivered by Sir Walter Fletcher, secretary of the Medical Research Council of Great Britain, on the evening of April 16. The title will be announced later.

The Brooklyn Cardiological Society will hold its third meeting at 102 Fort Greene Place, Brooklyn, N. Y., on March 31.

Gamma Mu Chapter of Kappa Psi Medical Fraternity was officially installed in Portland, Ore., on March 5. This chapter is made up of students of the Oregon Medical School.

The **Columbiana County Medical Society**, at its meeting held in East Liverpool, Ohio, March 8, elected the following officers for the ensuing year: *President*, Dr. P. C. Hartford, East Palestine; *Vice-President*, Dr. George P. Ikirt, East Liverpool; *Secretary-Treasurer*, Dr. C. R. Larkins, East Liverpool.

Vacancies for Clinical Psychiatrists.—The United States Civil Service Commission announces an open competitive examination for associate in clinical psychiatry and psychotherapy at St. Elizabeth's Hospital, Washington, D. C., at \$2,500 a year, and for other positions requiring similar qualifications. Applicants must have graduated with a degree from a college or university of recognized standing, with major work in social science or psychology, or as M. D. or Ph.D., and in addition must have three months' experience in work involving normal psychology. Applicants should apply at once for Form 2118, stating the title of the examination required to the United States Civil Service Commission, Washington, D. C.

Massachusetts Towns Offer Inducements to Physicians.—It is stated in the *New York Herald* that many small towns of Massachusetts are offering special inducements in the way of "cash bonus" in their efforts to attract young physicians to settle in them. More than seventy towns are without doctors. One town offers to give \$500 annually to the physician who will come there to practise. The authorities are getting in touch with the medical faculties of Harvard and other schools in the hope that graduates may be persuaded to settle in the smaller communities. It is estimated that the average country doctor in Massachusetts earns about \$2,000 a year.

Requests to Charity.—Of the \$2,500,000 bequeathed to various philanthropies by the late Mrs. Elizabeth Milbank Anderson, the New York Association for Improving the Condition of the Poor receives \$200,000; the Children's Convalescent Home at Chappaqua, N. Y., \$100,000; National Committee for Mental Hygiene, \$100,000; Henry Street Settlement, \$50,000; Adirondack

Cottage Sanitarium, \$25,000; State Charities Aid Association, \$25,000; Society of the New York Hospital, \$50,000.

Private Hospitals Opposed to Regulation.—A bill is before the Massachusetts Legislature which aims to place private hospitals under regulations of local boards of health. One of the provisions of the bill would permit abutters to prevent the establishment of a private hospital within 100 feet of their property. The purpose of the bill is to protect property owners from loss of value due to private hospitals conducted in such a manner as to cause depreciation in the value of surrounding property. The bill is meeting with vigorous opposition.

New Building for Doctors and Dentists.—Plans have been drawn for a unique cooperative physicians and dentists' office building at 141 East Sixty-fourth Street, New York. The structure will have five stories. Each floor will have a waiting room and five suites of offices. A plan of financing has been worked out so that with a comparatively small sum a desirable suite may be purchased and the annual payments for five years will be no more than the average rental prevailing for good office space. At the end of five years the annual payments, according to the plan, will be only \$1 a square foot. An executive committee selected by doctors will determine matters of policy.

Campaign to Raise Funds for Physicians' Home.—An association has been formed and a charter obtained at Albany for the purpose of establishing a home for aged physicians who find themselves in failing health and without funds. Practicing physicians throughout the country will receive an appeal for an annual subscription of \$10. Sustaining membership is \$100. Dr. Robert T. Morris, who has been largely instrumental in starting the movement is president of the organization.

Mount Sinai Hospital Buildings Progressing.—At a meeting of the trustees of Mount Sinai Hospital, New York, on March 19, it was announced that it would probably be another year before the new private pavilion, the new children's hospital, and the auditorium will be ready for use. The hospital had a deficit of \$50,842, for the year due to increased expenses. It was announced that ten perpetual beds had been endowed, one memorial bed, and one life bed. Legacies amounting to \$61,231 were received.

Rockefeller Board Aids Brussels University.—The Rockefeller Foundation has announced a contribution of 43,000,000 francs toward a budget of 100,000,000 francs for new buildings and endowments for the medical school of the University of Brussels. Part of the fund will go to the establishment of a nurses' training school in memory of Edith Cavell and of Madame Depage, who with the Queen of Belgium headed the activities of the Belgian Red Cross during the early part of the war. The classrooms of the new buildings will be on a new site on the Boulevard de Waterloo, adjoining the municipal hospital of St. Pierre, which will also be built and reorganized to serve as the teaching hospital of the university.

No Inebriate Hospitals.—According to a report

by Moratton M. Pollock, statistician of the New York State Hospital Commission, published in *Mental Hygiene*, no State hospitals for inebriates exists in the country, the last having been closed in 1920.

Obituary Notes.—Dr. JOSEPH RANSOHOFF, professor of surgery at the University of Cincinnati, died of heart disease at his home in Cincinnati on March 3, at the age of sixty-eight years. He was a graduate of the Medical College of Ohio, in 1872, and was made a Fellow of the Royal College of London in 1877. Dr. Ransohoff was a Fellow of the American College of Surgeons, and a member of the American Association of Surgeons, the Southern Surgical and Gynecological Associations, and the Western Surgical Association. He was on the surgical staff of a number of Cincinnati hospitals.

Dr. CHARLES C. LAMBERT, a graduate of the Baltimore University School of Medicine, in 1901, died at his home in Grandmount, Ia., on March 4.

Dr. JAMES MILTON STEADE, a graduate of the Cincinnati College of Medicine in 1894, died of heart disease in San Diego, Cal., on February 24, at the age of fifty-seven years. He was at one time president of the board of aldermen of San Diego and was a member of the city Board of Health.

Dr. E. H. BYRON of Lemoore, Cal., a graduate of the California Eclectic School, in 1900, died after a lingering illness, in a San Francisco hospital, in the latter part of February.

Dr. CARL WAGNER, a member of the Rush Medical College faculty and Chief Surgeon of St. Joseph's Hospital, Chicago, died at his home, on March 11, at the age of fifty-eight years. He was graduated from the University of Heidelberg in 1891, and was a Fellow of the American College of Surgeons. He was a member of the Chicago Pathological Society and the American Medical Association. Dr. Wagner was consulting surgeon to the Municipal Tuberculosis Sanitarium, Vice-president of the Medico-Legal Society, and a counselor for the Chicago Medical Society.

Dr. WALTER S. LINK of Parkersburg, W. Va., a graduate of the University of Maryland School of Medicine in 1897, died of cerebral hemorrhage in a local hospital on March 6. He served in the late war as captain in the Medical Corps.

Dr. J. D. DUNLOP of Alpena, Mich., a graduate of New York University Medical School, in 1884, and of the University of Toronto, in 1887, died at his home about March 1.

Dr. BRUCE FFOULKES of San Francisco died in a local hospital as the result of being gassed during action in the St. Mihiel sector during the world war on March 4, at the age of forty-seven years. He was Lieutenant-Colonel of the Three-hundred and Fifty-ninth Sanitary Train, and was gassed when the Germans shelled a hospital of which he was in charge. He was graduated from the Cooper Medical College, Calif., in 1894.

Dr. STANLEY P. BLACK died at his home in Pasadena, on March 5, at the age of sixty-two years. He was graduated from the Northwestern University Medical College in 1885. He was a member of the American Academy of Medicine, the American Association for the Advancement of Science, one of the founders of the Los Angeles Clinic, and a trustee of the Barlow Medical Library.

Dr. ERNST LEDERLE, twice Health Commissioner of New York City, died of septic poisoning at a sanatorium in Goshen, N. Y., on March 14, at the age of fifty-six years. Dr. Lederle was Health Commissioner of New York City from 1902 to 1904 and again from 1910 to 1914. Dr. Lederle was not a physician, but an expert chemist. He was graduated from the Columbia University School of Mines in 1886 and later received from the University the degrees of Ph.D. and Sc.D. He established the Lederle Laboratories and Lederle Antitoxin Laboratories. He was a member of the Society of Chemical Industry and the American Chemical Society.

Dr. CHARLES MAITLAND MANN, a graduate of Cornell Medical School in 1907, died suddenly at his home in Petersburg, N. Y., on March 7, at the age of thirty-seven years. He served in the Medical Corps of the United States Army during the world war, at United States Hospital 16, New Haven, Conn.; Camp Jackson, Columbia, S. C., and Spartansburg. He was formerly visiting physician at St. Joseph's Hospital, New Rochelle, N. Y.

Dr. SILAS PIERSON LEVERIDGE, a graduate of Bellevue Hospital Medical College in 1880, died of pneumonia at his home in New York City on March 16, at the age of sixty-five years.

Dr. WALDO J. LUSSIER of Woonsocket, R. I., died on March 11, at the age of forty-two years. He was a graduate of the College of Physicians and Surgeons, N. Y., in 1911, and was a member of the American Legion and Veterans of Foreign Wars.

Dr. WILLIAM D. BOOKER, formerly clinical professor at Johns Hopkins Medical School, died at his home in Baltimore on March 15, at the age of seventy-five years. He was a graduate of the University of Virginia in 1867. He was made Professor Emeritus of Johns Hopkins in 1909. Dr. Booker was a member of the American Pediatric Society and the American Medical Association.

Dr. DANIEL V. FAHEY, a graduate of the Long Island College Hospital in 1919, resident surgeon of St. Catherine's Hospital, Brooklyn, N. Y., died of epidemic encephalitis, on March 18, at the age of twenty-nine years.

Dr. A. B. NELSON of Arcadia, La., died in Albuquerque, N. M., on February 27, at the age of forty-six years. He was graduated from the Memphis Hospital Medical College in 1902, and studied in Europe for two years.

Dr. ARTHUR G. HOBBS of Atlanta, Ga., a graduate of the Louisville University School of Medicine in 1877, and professor of diseases of the ear, eye, and throat at the Southern Medical College, died at his home on March 9, at the age of sixty-seven years. Dr. Hobbs was president of the American Rhinological Association in 1891.

Obituary.

SIR FELIX SEMON, K.C.V.O., M.D., F.R.C.P.

LONDON.

SIR FELIX SEMON died March 1, at Rignalls, Great Missenden, England, at the age of 72 years. He was born at Danzig on December 8, 1849. He began his medical studies at Heidelberg in 1868, and took the M.D. degree at Berlin in 1873. He then studied

in Vienna and Paris, devoting his attention more particularly to diseases of the throat and nose, and becoming expert in the use of the laryngoscope, then recently introduced into medicine.

He then settled in England, and was admitted a member of the Royal College of Physicians in 1876, and a fellow in 1885. In 1894 the German Emperor conferred on him the title of Royal Prussian Professor, the Order of the Red Eagle having been given him in 1888. He was one of the founders of the Laryngological Society and was elected President for the years 1894-6. At the Diamond Jubilee in 1897 he received the honor of knighthood, and in 1902 he was decorated C.V.O., being advanced to K.C.V.O. in 1905. In 1901 he was appointed Physician Extraordinary to King Edward VII. During the war he remained loyal to his adopted country. Semon continued to enjoy a large laryngological practice until 1911, when he retired. British laryngologists and many of his foreign confrères then collected a sum of £1,040 as a testimonial, which he presented to the University of London to establish a fund for the award of a commemorative bronze medal for the best work in the treatment of diseases of the throat and nose, and to found the "Semon Lectureship in Laryngology." In 1884 he founded the *Internationale Centralblatt fuer Laryngologie und Rhinologie*, and for 25 years acted as its editor.

By his skill, his untiring energy, and his honesty of purpose Semon did much for laryngology in England. He found it in its infancy; he left it an important and flourishing specialty. It was perhaps owing to his initiative that it long maintained a closer relationship with Berlin and Vienna than any other branch of medicine or surgery. His own work was done chiefly in connection with cancer of the throat and with the functions and diseases of the motor nerves of the larynx.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, February 28, 1920.

The Influenza Epidemic.—Dr. H. Kenwood, in his annual report as medical officer of health for the county of Bedford for the year 1919, made some interesting remarks on the recent influenza epidemic, which caused a civilian mortality throughout the country at the rate of 4,774 per million per annum, an epidemic mortality not equalled in Great Britain since registration commenced. Nor did this heavy mortality truthfully represent the ravages of the disease; for the deaths attributed to pneumonia, bronchitis, heart disease, and phthisis were also markedly increased as the consequence of the influenza infection. Moreover, the age distribution of the attacks and of the deaths markedly departed from that of previous epidemics. From 15 to 25 were the years of highest mortality in the epidemic of 1918-19; whereas the most fatal years of previous epidemics were those of 55 and over. In Dr. Kenwood's view inoculation is of value in protecting against fatal complications rather than against attacks of the disease. The Ministry of Health

has made a vaccine available for distribution through medical officers of health to medical practitioners, and doubtless in the event of another epidemic this precautionary measure will be widely adopted. The epidemic showed the need of a promptly available supplementary personnel for temporary employment in time of public health emergency. Nurses are required in epidemics of influenza, measles, and whooping cough who can visit all the poorer homes in which it has been ascertained that such diseases have occurred, and it would be well if these services could be supplemented by a voluntary personnel suitably trained to offer good advice and to make inquiry with the view of ascertaining which cases were really necessitous. Recent war experience has shown that there are in every community persons who would be able and willing to volunteer for such emergency services if they were invited to do so. Dr. Kenwood thinks that the suffering and mortality in an influenza epidemic could be materially reduced by adequate nursing assistance; a provision of fuel, food, and clothing to really necessitous cases; by hygienic advice, more particularly as to ventilation and the placing out of the rest of the family; the distribution of a suitable disinfectant with directions as to its use, and the provision of more hospital isolation and treatment.

Proposed State Control of Vaccines and Drugs.

—Provision for the supervision and control of therapeutic substances which cannot be tested adequately by chemical means is recommended by a Ministry of Health Departmental Committee, presided over by Sir Mackenzie Chalmers. The substances in question include vaccines, serums, toxins, antitoxins, and analogous products, salvarsan and its analogues, and various drugs. It is proposed that the controlling authority should be the Committee of the Privy Council appointed on March 11, 1920, under powers conferred by the Ministry of Health Act, 1919, and that the main functions of the committee should be to decide from time to time what substances are to be brought under control and to prescribe the methods of standardization and testing for these substances. It is further proposed that there should be a control laboratory, under Government control, wherein standards would be prepared and maintained; research carried out in connection therewith, and tests made to ascertain that the products issued by manufacturers conform with the standards laid down. The Medical Research Council, who already possess the requisite organization, should be responsible for this central laboratory. The method of control should include the licensing of manufacturers, inspection of their plant, premises, and processes, and the testing of the finished articles. Products made abroad should be subject to similar restrictions.

Prevention of Venereal Disease.—The report of the special committee appointed by the National Council of Public Morals at the request of Dr. Addison, the Minister of Health, was published a short time ago. This committee included men and women, medical and lay, of opposite views with regard to the best means of dealing with the venereal problem and especially with respect to

the most effectual measures of prevention. In spite of this fact the committee has presented a unanimous report, although some of the conclusions or rather recommendations are not very definite. For sometimes, as noticed in these letters on several occasions, the efforts to prevent venereal disease, which after all seems to be the only way to abolish it, have been baffled by divergent views as to the provision of facilities for immediate disinfection. On the committee of which the Bishop of Birmingham was chairman, were laymen and medical men who held quite different opinions, and it is therefore encouraging to know that a unanimous report was rendered. It is to be hoped now that a common understanding may be come to between the moral and medical advisers of the country, as it is mainly the moral aspect of the question which has hindered any agreement with regard to immediate disinfection or self-disinfection. So long as there exists disagreement between eminent members of the medical profession on this point just so long there cannot be widespread cooperation of the public and therefore no national effort is possible which alone can make a success of any method. Of course it is obvious that chastity is the best safeguard against the spread of venereal disease, but at the same time it is freely recognized by even those who lay stress on the moral side of the matter that a large number of persons male and female pay no attention to moral appeals, but indulge more or less frequently in promiscuous intercourse, thereby incurring the risk of contracting and spreading the disease. Moreover, the evil does not end with them, but is spread with disastrous results among innocent women and children. The war, too, has rendered individuals more prone to promiscuous intercourse and less amenable to teachings of religion or to moral law. As for the medical aspects of the situation the report appears to be sufficiently clear. It is stated in a definite manner, although as said before there is a certain amount of "hedging" that for a considerable proportion of the population means for disinfection should be provided as quickly as possible after sexual intercourse either by the man concerned, or by or under the supervision of a medical practitioner or trained assistant. And it is pointed out that the results obtained in preventing the development of the disease will depend largely on, it might almost have been said wholly on: (1) The interval of time which elapses between exposure to risk and the application of the disinfectant substances, and (2) The care and thoroughness with which the disinfecting process is carried out. It is known that if a disinfectant is applied properly within a short time after intercourse the infective agent is destroyed, but such a disinfectant should be applied as soon as possible after intercourse. An important question arises in connection with providing a civilian population with facilities for immediate disinfection. Will those requiring disinfection make a prompt use of these facilities, if they are supplied at ablation or early treatment centers. Opinions of members of the committee did not agree on this point. Evidence was given that in the case of soldiers, at any rate, careful instruction as to

self-disinfection had the desired effect and could be relied on to prevent the development of the disease. However, a civilian population differs very considerably from an army and it seems that a good deal of educational propaganda will have to be undertaken before the mass of the population realize the necessity for prompt and careful self-disinfection. The committee considered that no difficulty should be placed in the way of either (1) The spread of knowledge as to the use and value of disinfectants; or (2) The obtaining by individuals of such disinfectants from druggists or other sources. The moral aspect is discussed at length in the report but the evils of self disinfection are not so greatly emphasized as formerly when the matter has been debated by opponents of the method. It appears as if a compromise or understanding may be reached between the Society for the Prevention of Venereal Disease, which has consistently advocated the provision of facilities for self-disinfection, and the National Council for Combating Venereal Disease, which has opposed this policy.

Hospital Libraries.—A largely attended meeting took place in the London Library on Feb. 27 in support of the movement so successfully begun during the war by the British Red Cross Society in supplying books to the military hospitals. Now that this organization is dealing with the needs in illness of the civilian population, it is hoped to place the effort upon a permanent basis and to establish libraries in all hospitals, infirmaries, and asylums. General Sir John Goodwin, well known in America, who spoke at the meeting, said that after thirty-two years' experience of hospitals he now made a point of demanding a library in connection with such institutions. In a hospital in France, through which 58,000 officers and men had passed, the books had been an incalculable help and they would be the same to civilians who were dreading or recovering from severe operations.

LETTER FROM BELGIUM.

(From Our Special Correspondent.)

LIEGE, February 15, 1921.

Reforms of the Sanitary Service.—The Sanitary Service of the Army has instituted a series of reforms the result of which will be greatly to the benefit of this important branch of the service. Before the war financial difficulties prevented the carrying out of certain scientific projects. But the terrible experience we have passed through has opened many eyes. At present the young medical students of service age are able to enter into an eight-year engagement during which they can continue their studies while rendering to the army services which do not interfere with their work. Those in the upper classes in the university can enter into a similar arrangement, but they have the rank of adjutant or second lieutenant, according to their place in the school. In consequence of this the vacancies created by the licensing of the medical volunteers have been almost all filled. Evidently we shall have to wait some years before being able to establish a complete system, especially as relates to the encouragement of the

young in scientific studies, the stability of the special services in the hospitals, the creation of research laboratories, etc. What is essential now is to attract workers and to make teachers of them in order to create a military medical school worthy of the name and worthy of the army to which they will have to dedicate their activities.

The Effect of Tubal Pregnancy on the Adnexa of the Opposite Side.—At a recent meeting of the Belgian Society of Obstetrics and Gynecology Dr. Keiffer reported a case of tubal pregnancy in which the symptoms pointed to the existence of tubal lesions on the other side of the body. He thought that the lesions were the consequence of the extrauterine pregnancy, but most of those who took part in the discussion were of the opinion that lesions were present on both sides and that it was their presence that determined the lodgment of the ovum in one or the other tube. These tubal lesions were as a rule of gonorrheal origin. At the same meeting Dr. Brouha reported an interesting case of fatal uteroplacental apoplexy occurring at the beginning of the sixth month, manifesting itself by extensive infiltration of capillary origin in the uterine wall. At autopsy grave and extensive lesions of the liver and kidneys were found, showing that the woman was in a state of toxicaemia which usually finds external expression in eclampsia.

Albee's Operation for Pott's Disease.—At a recent meeting of the Belgian Surgical Society Mme. Derscheid and M. Delchef of Brussels presented two children with Pott's disease of the spine who had been operated upon by Albee's method. The value of these interspinous grafts was still undecided; they would be useful only if they gave speedy and definitive protection against external shocks. Albee's opinion that the osseous graft remains alive and grows was not accepted by many, and the two cases here reported confirmed radiologically this negation. The patients were a girl of 8 years and a boy of 10, operated upon at the termination of spondylitis, which had lasted four years. The operative indication was that they could not dispense with the supporting jacket. The clinical result was in each case excellent, and the children were able now to walk without support. But the x-ray pictures showed that the grafts began to be absorbed in from six to eight weeks, and at the end of six months this absorption was already far advanced. The general condition of the two children had greatly improved, but the deformity had increased. The authors concluded from this that in a case of still active Pott's disease the bony support would be insufficient. He insisted upon the necessity of repeated x-ray examinations before coming to a final judgment regarding the results of Albee's operation. They thought possibly the Nageotte grafts, the absorption of which is less rapid, would be more efficacious.

In discussing this report M. Maffei of Brussels said it should be noted that Albee's principal object in employing bone grafts was the correction of the deformity; but in Pott's disease we have to consider the tuberculous lesion as well as the deformity, and it seems to be on the former especially that the graft acts by a sort of cellular

action (cytotherapy). Maffei agreed with the previous speakers that the graft was almost always absorbed; at the end of two years, out of 35 cases operated upon the graft persisted in only two. He had observed that when the gibbosity increased in these grafted cases it assumed the form of a rounded curvature and was not angular.

Renaissance of the Belgian Universities.—We have previously spoken of the change brought about in the intellectual life of Belgium by the millions of francs donated by America. These millions were divided among the State universities. Also there is a "University Foundation" with headquarters in Brussels which distributes judiciously various sums, under the name of loans, to needy students in the four State universities. It is understood that the loan will be repaid, without interest, within fifteen years at the latest. But the Free University of Brussels has also received a magnificent gift from America. Following the visit to America of the Brussels Medical Mission, composed of MM. Bordet, Depage, Sand, and Dustin, the Rockefeller Foundation, generously seconding the favorable disposition of public opinion in America, promised a gift of forty million francs to the medical school on condition that the Communal Council would undertake to defray any additional expenses. Just now American delegates have come to Brussels asking that the questions raised by this offer be studied and answered as soon as possible. Under this stimulus the Municipal Council has taken the necessary steps for fulfilling the conditions mentioned. And already St. Peter's Hospital is about to be demolished in order to be rebuilt in accordance with the modern views of hospital construction.

The Médico-Chirurgical Society of Liège.—At the annual meeting of the Société Médico-Chirurgicale de Liège, held February 9, the election resulted in the selection of M. Brouha of Brussels, president; M. Hougardy, first vice-president; M. Stockis, second vice-president; M. Cahay, treasurer; M. Delrey, secretary. The scientific session was opened by Dr. Roersch, who presented a detailed clinical study of perforating gastric and duodenal ulcers. He showed by general and personal statistics the advantages of early operation, and on the other hand the prognosis becomes more and more grave in proportion to the length of time that operation is delayed.

2. The Schick Test and Immunization with Diphtheria Toxin-Antitoxin.—Benjamin White makes the following recommendations: 1. All persons over 18 months of age in the entire community should have their susceptibility to diphtheria determined by means of the Schick test, and the reaction which they show should be noted either in institutional records or in the records of the

family physician. 2. In infants below 18 months of age the Schick test is not necessary because a negative reaction may give rise to a false sense of security. Very young infants may exhibit a negative Schick test owing to the immunity passively acquired from the mother, but, inasmuch as this type of immunity is transient, it is safer to assume that no child under 18 months possesses permanent immunity. 3. All infants below 18 months of age accordingly should be actively immunized with three doses of 1.0 c.c. of diphtheria toxin-antitoxin mixture, irrespective of the reaction to the Schick test which the infants might show at the time of immunization. The doses should be 0.5 c.c. for babies under six months of age and 1 c.c. for all others. 4. All persons over 18 months of age who give a positive Schick test should be immunized by receiving three subcutaneous injections of 1 c.c. each of toxin-antitoxin at intervals of seven days. 5. All persons immunized by this method should be retested three months after the last injection, and reimmunized if they should by any chance still give a positive Schick reaction.

3. **The Functions and Scope of an Industrial Clinic in a General Hospital.**—Harry Linenthal bases this communication on experience in the industrial clinic of the Massachusetts General Hospital. He points out that physicians in general have little or no familiarity with industrial processes or conditions, and as a rule have little interest in them. The industrial clinic can thus be of help to them by pointing out the etiological factors in industry responsible for certain pathological states which would otherwise remain obscure and unrecognized. This bringing to light of the etiological factors which exist in the health hazard to which a patient may be exposed at his work and which is wholly or partly responsible for the symptoms for which he presents himself for treatment is the chief function of the industrial clinic. Moreover, cases of industrial disease present many problems which do not arise in the treatment of the ordinary patient. It is necessary that a person suffering from ill health resulting from industrial conditions be registered and followed up by a clinic interested and competent to deal with the case in all its social and industrial ramifications. The patient should be referred to other clinics when special treatment is necessary. The industrial clinic in the general hospital permits of the grouping of cases and, by the frequent repetition of observations in the same class of workers, suggests new problems. It also permits the analysis of accumulated records and inferences as to the effects of certain occupations, and may thus increase knowledge of the effects of occupation on health. Other functions of the industrial clinic are the training of students in this comparatively new field of hygiene, the investigation of problems in industrial disease, and the bringing about of changes in industrial establishments so as to make hazardous processes safer. There is no agency at present more capable, with the aid of other special clinics in the hospital, of handling the problems that arise in connection with those crippled or made ill by industry. No agency is so well equipped and able to correlate occupations with the physical condition of the worker and thus serve a reliable and accurate source

of vocational guidance to those incapacitated by industry. Finally, it may be pointed out that an industrial clinic, with its group of physicians and social workers trained in industrial problems, brings the hospital in closer contact with social and economic conditions outside the hospital walls than is possible for any other clinic, and thus furnishes an avenue for aggressive work on the part of the hospital beyond its walls for the prevention of social conditions. The writer cites cases illustrative of the possible industrial etiology of skin diseases, respiratory diseases, and occupation strains. He emphasizes the point that the great function of an industrial clinic is to trace the part industry plays in producing the more common diseases seen in all classes of the community. If the effects of industry were only in the production of the specific occupational diseases, the problem would be comparatively easy and relatively unimportant. Easy, because the casual relationship between the industrial condition and the resulting disease is manifest. Relatively unimportant, because the number of workers engaged in processes giving rise to specific industrial diseases are few in comparison with the vast army of workers exposed to less specific hazards of irritating dust or fumes, of localized fatigues, of insanitary conditions, or who are constantly subjected to the monotony and general fatigue effects of modern industry.

5. **Relative Effectiveness of Various Forms of Treatment in Neurosyphilis.**—Stokes and Osborne, from their observations on the comparative value of routine intravenous treatment, spinal drainage and arspenaminized serum intraspinally (Swift-Ellis), reach the following conclusions, which they do not consider necessarily final: 1. A comparison of the findings on patients receiving spinal drainage in conjunction with arspenamin intravenously and routine mercurialization, and the findings on patients receiving an equal amount of routine treatment without spinal drainage, demonstrates no superiority in favor of the drainage method. 2. The most immediate change produced by either of these methods of treatment is in the cell count. 3. A transient but marked rise followed by a fall toward normal limits occurred in patients receiving spinal drainage, and there is reason to believe that a similar Herxheimer-like curve of pleocytosis accompanied by transient exacerbation of symptoms occurs in many patients under treatment for neurosyphilis by routine methods. 4. Temporary rise in the cell count early in the course of treatment should not therefore necessarily be regarded as of unfavorable prognostic significance. 5. In ten patients in whom spinal drainage had produced indifferent results, the administration of arspenaminized serum intraspinally some months later produced what appeared to be more and more permanent results.

11. **Organ Stimulation by the Roentgen Ray.**—Petersen and Saelhof record experiments with the stimulation of the liver, the kidney and the pancreas by means of the Roentgen ray, and discuss the clinical application of their findings. From these observations they conclude that the Roentgen ray, in proper dosage, has the property of stimulating cellular metabolism. When organs are selectively stimulated by Roentgen rays, therapeutic results can be achieved either by direct stimulation of an external secretion (the kidney) or of an internal secretion (the pancreas in diabetes). A second method of possibly influencing remote pathological lesions lies in the mobilization of antibodies, enzymes, and thromboplastic substances following selective organ stimulation. The effects on tuberculosis (irradiation of the spleen), on hemophilia and purpura (irradiation of the spleen) and some of the effects on malignant tissues can possibly be examined from this point of view with profit. It is probable that the indications of Roentgen-ray therapy in the treatment of internal diseases will find marked extension if proper recognition is given the possibility of organ stimulation by such physical means.

2. **An Address on Skin Disease in Relation to Internal Disorder.**—Sir James Galloway, in discussing the cutaneous manifestations which must be considered as phases or results of a general infective process or of some internal disorder, draws attention first to the erythema group, a class sufficiently well defined for purposes of clinical recognition. The discussion does not involve the various forms of reddening produced by merely local mechanical or bacterial reactions. On the other hand, the manifestations of this group may be not only erythematous but also urticarial, exudative, vesicular, and hemorrhagic in character. Under this head are considered acute exanthematous diseases; the action of alien proteins; exudative erythema; disorders of the gastrointestinal tract; erythema nodosum; lupus erythematosus; the pemphigoid group. Diseases of the skin associated with functional disturbance of the blood-vessels which come within the category under consideration are thromboangiitis obliterans and permanent dilatation of arteries and capillaries. The nervous system, both central and peripheral, has long been held responsible for exerting influences on diseases of the skin, among which are herpes zoster and syringomyelia. Considering the skin in relation to disorders of abdominal and other viscera the writer deems it a matter of surprise, considering the close physiological relationships which exist between the kidneys and the skin, that disease of the kidney is not more often associated with manifestations on the skin. Very few examples come to mind of skin outbursts occurring in the course of renal disease. In cases of severe disease of the skin, especially in cases of exfoliative dermatitis, albuminuria and nephritis occur. This complication has been frequently noted in the case both of children and of adults. The presumption in such cases is that the cutaneous disease and the renal disorder are manifestations of the same toxic cause, and that it is not correct to assume that the symptoms on the skin are caused by the disease of the kidney. Of the many remarkable manifestations on the skin occurring during the course of disorders of metabolism one of the most interesting is xanthoma. Pigmentary changes in the skin have long been associated with the health of the patient. Disorders of the glands of internal secretion are to be taken into consideration in this connection. Reference is made, in closing, to the change in the skin associated with disease affecting the structure of the blood and certain hitherto unknown lymphatic glands. Lymphatic leucemia and the lymphogranulomatosis known as Hodgkin's disease may be taken as examples.

5. **Auricular Fibrillation.**—D. S. Brachman bases this contribution on 400 cases, 110 of which were in-patients and 290 out-patients. The youngest was 16 years of age, the oldest 76. No less than 25 per cent. of all patients admitted to the wards of the National Hospital for Diseases of the Heart have auricular fibrillation, yet approximately 8 cases out of 10 are not recognized prior to admission, whereas even without polygraphic or electrographic help not more than one out of 10 should be missed. From his study of this series the following conclusions are drawn: 1. The three most constant and diagnostic signs found in auricular fibrillation are: (a) the irregular irregularity in rhythm, (b) enlarged transverse diameter of the heart, (c) a difference in the apex- and pulse-rate. 2. An irregular heart rhythm is almost pathognomonic of auricular fibrillation. It must be differentiated from that found in (a) multiple premature beats, especially those of auricular origin, and (b) sinoauricular heart-block. 3. There are no symptoms pathognomonic of auricular fibrillation, nor are there any more suggestive of this than of other cardiac conditions. 4. A diagnosis of auricular fibrillation having been made it is essential to consider (a) the pathological condition of the heart which led to this condition, and (b) the effect that the fibrillation will have on the circulation as a whole, and especially on the left ventricle. 5. It is desirable

to decide whether there is myocardial change in the auricles alone, or whether the ventricles also are affected. If the latter is the case, the prognosis is distinctly worse. 6. The main object to be achieved when treating auricular fibrillation is to adjust the rate of the ventricles so as to produce an adequate circulation without undue ventricular work. 7. The great therapeutic agent is rest—physical, mental, and cardiac. 8. The commonest antecedent disease is rheumatic fever. Rheumatic fever or chorea was found in 39 per cent. of the total number questioned, while 19 per cent. of the total gave a history of no previous illness. Graves' disease very definitely leads to fibrillation. 9. Primary myocardial involvement was found in as many cases as were associated with pure mitral stenosis. The other conditions in the order of their frequency were mitral regurgitation, both mitral and aortic disease, and lastly, aortic disease alone. 10. Fibrillation of the auricles can continue until the auricles are completely exhausted and become practically a passive chamber. The contractions may then come on only occasionally and be very slight, but impulses will still be transmitted to the ventricles. 11. There is no predisposition in either sex towards fibrillation. 12. As the pulse-rate usually does not give the ventricular rate of contraction, it is necessary in all cases of auricular fibrillation to count the apex-rate as well. 13. A murmur presystolic in time can be heard in some cases of auricular fibrillation associated with mitral stenosis, but this is usually due to a diastolic murmur running into the following systole when the rest period is short.

1. **Vaccine Therapy in regard to General Practice.**—Alexander Fleming has been practising vaccine therapy since it was in its infancy, and as time goes on he finds himself more and more convinced of its efficacy, not only for the more severe cases which are to be seen at a hospital, but also and more especially for the lesser ailments which seldom appear at a hospital, but with which the practitioner has much to do. He defines vaccine as a substance which, when injected into the animal body, induces the formation of specific antibodies. The term "vaccine," therefore, is synonymous with the word "antigen." In relation to the question of whether a stock or an autogenous vaccine should be used, four different classes of cases must be considered: Class 1. Where the vaccine is to be used for prophylaxis. Here there is no choice—only a stock vaccine can be used. Class 2. Where the nature of the bacterial infection is known but a culture of the microbe cannot readily be obtained from the patient. In such cases, again, there is no choice, and stock vaccines must be used. Class 3. Where, owing to the profusion of contaminating microbes, it is difficult to identify and differentiate with sufficient sharpness one microbe from another of the same morphological species. Here only an experienced bacteriologist will be able to make satisfactory autogenous vaccines. Class 4. Where the infecting microbe can easily be obtained from the patient in pure culture. A stock vaccine is indicated when the infecting organism belongs to a group the members of which differ very little among themselves. Thus, in staphylococcus infections, a stock vaccine will in almost all cases give as good results as an autogenous, and in some few cases the stock vaccine will prove the more beneficial. It is desirable to use an autogenous vaccine (a) when the infecting agent belongs to an ill-defined group of microbes. This is well exemplified in the so-called "B. coli infections," for the name is loosely applied to a large group of organisms which, as regards their antigenic properties, are very different. It is therefore more satisfactory in such infections to employ an auto-

genous vaccine. (b) When the infection is severe and it is felt to be too great a risk to wait to see whether the stock vaccine is effective; but it is wise in such cases to give a small dose of the stock vaccine while the autogenous one is being prepared. (c) When treatment with a stock vaccine has failed. The clinical effects of the injection of a bacterial vaccine may be divided into two classes: (a) toxic, and (b) immunizing. The clinical application of vaccine therapy is considered particularly with respect to catarrhal infections of the respiratory tract (the common cold, bronchitis, influenza); pneumonia; whooping cough; chronic rheumatic conditions; diphtheria carriers. It is pointed out that patients may be inoculated with bacterial products not only from without, but also introduced into their circulation by some disturbance of the infected focus. It has been shown by means of blood examinations that any such disturbance is followed by a sequence of events which are the exact counterpart of those following the administration of vaccines by hypodermic injection. In the treatment of any patient by vaccines a satisfactory conclusion is to be arrived at only if the phenomenon of autoinoculation is considered, and in most cases it is necessary that these autoinoculations should be diminished or abolished by keeping the infected part as much as possible at rest by splinting or some other means.

5. The Controlling Factors in Amphibian Metamorphosis: A Review. John F. Fulton, Jr.

1. Adenoma of the Thyroid with Hyperthyroidism (Thyrototoxic Adenoma).—Walter M. Boothby traces the history of the recognition of this disease as a clinical entity, and studies the symptomatology with basal metabolic rates. He summarizes his findings thus: 1. According to Plummer's classification there are two separate and distinct types of hyperthyroidism, each due to a different pathological change in the thyroid gland: in the one type, the hyperthyroidism associated with the clinical syndrome of true exophthalmic goiter is always accompanied by diffuse hypertrophy and hyperplasia of the thyroid gland, in the other type the hyperthyroidism, not associated with this typical diffuse hypertrophy and hyperplasia, but with the occurrence of adenoma in the gland, is due to the adenoma, and the resulting clinical syndrome is distinguishable from that occurring in true exophthalmic goiter. 2. The syndrome associated with the hyperthyroidism from adenoma of the thyroid is considered by Plummer to be a distinct clinical entity and may be defined as a disease associated with adenoma, characterized by an increased basal metabolic rate excited by an excess of the normal thyroid hormone in the tissues. About middle age the adenomatous tissue gradually begins to furnish an excessive amount of the apparently normal thyroid hormone (thyroxin) and this produces the increased metabolic rate and intoxication clinically evidenced by nervousness, tremor, tachycardia, loss in strength and weight, and a tendency to hypertension, and in the later stages myocardial disintegration. The underlying cause or stimulus that activates the thyroid to adenomatous growth and over-secretion is not known. 3. Detailed metabolic rate and blood pressure studies are reported in seventy-five cases of adenoma with hyperthyroidism in which the average basal metabolic rate before treatment was + 35 per cent. and after operation + 7 per cent. Similar studies of 201 cases before treatment are also given in which the average basal metabolic rate was + 28 per cent. In contrast the average basal metabolic rate in 167 cases of adenoma without clinical evidence of hyperthyroidism was + 2 per cent.; in eighteen of these cases the average basal metabolic rate before

operation was — 4 per cent. and it remained practically unchanged, — 8 per cent., as a result of thyroidectomy. 4. Three groups of exophthalmic goiter cases of varying degrees of severity were studied. In thirty-six patients with the severest type of the disease the average metabolic rate before treatment was + 66 per cent.; these patients were subjected to rest in bed and two ligations at an interval of a week or more and within ten days after the second ligation the basal metabolic rate was — 50 per cent. After three months' rest at home these patients returned to the clinic and were found to have an average basal metabolic rate of + 42 per cent., with corresponding clinical improvement; within two weeks after thyroidectomy the rate had dropped to + 19 per cent. In a second group, fifty-two moderately severe cases, the patients were subjected to a single ligation and thyroidectomy one to two weeks later. The basal metabolic rate before treatment was + 52 per cent., after thyroidectomy + 15 per cent. In twenty-two the basal metabolic rate before treatment was — 57 per cent. and ten days after the preliminary ligation was + 41 per cent.; within two weeks after thyroidectomy the basal metabolic rate in this group had fallen to — 16 per cent. In fifty-two patients with mild exophthalmic goiter on whom a primary thyroidectomy was performed the average basal metabolic rate before treatment was + 36 per cent. and two weeks after operation + 8 per cent.

1. Tapping of the Heart. Y. R. LeMonnier.
2. Congenital Malformation of the Anus and Rectum, with Report of Cases. E. D. Fenner.
3. Vertigo or Dizziness. S. C. Jamison.
4. Occipito-Posterior Positions. E. L. King.
5. Menace to Public Health. Oscar Dowling.

1. Tapping of the Heart.—Y. R. LeMonnier reports a case of supra acute pericarditis in which he tapped the heart, with the result that the patient lived, but an organic affection of the heart immediately supervened. This case was observed in 1875, and as he has not seen another since he concludes that these cases, immediately accompanied with or followed by valvular troubles, dropsies, embolisms, paralyses, etc., are fortunately rare.

Influenza Studies; Further Data on the Correlation of Explosiveness of the 1918 Epidemic.—Raymond Pearl says that in the first of these studies, published in the fall of 1919, a definite and sensible correlation was established between the explosiveness of the outbreak of influenza in 1918, as measured by an epidemicity index, and the normal death rate from certain organic and chronic diseases. The present, more critical study, attempts to determine by multiple or partial correlations the chief factors for the great variation in explosiveness in 34 American cities. New indexes are employed and every effort is made to get critical quantitative measures of the variables involved. In general the second study confirms the first; and the author believes that the critical refinements introduced fully meet all earlier criticisms. He maintains that the correlation between the death rate from organic diseases of the heart and explosiveness of the influenza outbreak is extremely significant. He points out that the normal death rate from pulmonary tuberculosis and the explosiveness of the epidemic, though sensibly correlated, are not markedly so; and that the death rates from cancer and typhoid fever show no sensible correlation. Moreover, of the six environmental and demographic variables considered, only one, the latitude of the city, shows any correlation with the epidemic; and the significance of this is held to be doubtful. A similar correlation between deaths from influenza and those from cardiac diseases was also found, but not between influenza and acute nephritis, Bright's disease, or tuberculosis. The author concludes that the results indicate clearly that explosiveness of outbreak and total destructiveness are distinct but related epidemiological characteristics.

Book Reviews.

PSYCHOPATHOLOGY. By EDWARD J. KEMPF, M.D., Clinical Psychiatrist to St. Elizabeth's Hospital (Formerly Government Hospital for the Insane), Washington, D. C.; Author of "The Autonomic Functions and the Personality." 87 illustrations. St. Louis: C. V. Mosby Company, 1920.

THE Author of this book, which is interesting, even if not to be taken seriously by all readers, starts out with the assumption, which he calls a fact, that "Man is a species of ape that has gradually developed an intricate social system of laws and beliefs which direct the gratification of the individual's affective cravings." With this as a premise it is easy to go on to show that the conventions which this reformed ape has established and the punishments which he has decreed for those who run counter to them have created a fear of tabooed cravings within himself, the struggle to control which establishes functional neuroses or psychoses. Then the door is opened wide and Freud finds himself entirely at home.

As in all books written by Freudians, the impression is given that every trivial or serious deviation from normal mental processes has a perverted sex basis—in other words, *cherchez l'infame*. Even the poor sufferer from delirium tremens overcome by his fear of snakes and the like, "is the victim of his homosexual cravings to be sexually overcome by a potent male!" We presume the professional psychoanalyst is free from repressions, transferences, and the like, but the author of this book does not hesitate to accuse the critics of psychoanalysis of such, or to accuse those who do not practise this form of suggestion as influenced by financial considerations in keeping the yearning neurotic attached to them.

The book is of value to one who wishes to learn the Freudian conception of insanity, but it will not help one who seeks an all-around sane view of mental disease; neither does it serve those who are looking for an exposition of the technique of psychoanalysis. But it is the best, as it is the latest, authoritative treatise on sexual psychopathology.

THE DIFFICULTIES AND EMERGENCIES OF OBSTETRIC PRACTICE. By COMYNS BERKELEY, M.A., M.D., M.C., Cantab., F.R.C.P. Lond., M.R.C.S. Eng., Obstetric and Gynecological Surgeon to the Middlesex Hospital; Surgeon to In-Patients, Chelsea Hospital for Women; Senior Obstetric Surgeon, City of London Lying-In Hospital; Gynecological Surgeon, Eltham and Nottingham Hospital; Lecturer on Obstetrics and Gynecology, Middlesex Hospital Medical School; Examiner in Obstetrics and Gynecology to the Universities of Oxford, Cambridge, London, Manchester, and Sheffield; Sometime Examiner in Obstetrics and Gynecology to the University of Leeds and the Conjoint Board of England; and VICTOR BONNEY, M.S., M.D., B.Sc. Lond., F.R.C.S. Eng., M.R.C.P. Lond.; Assistant Obstetric and Gynecological Surgeon to the Middlesex Hospital; Lecturer on Practical Obstetrics, Middlesex Hospital Medical School; Surgeon to the Chelsea Hospital for Women, the Freemason's Hospital; Gynecological Surgeon to the Miller Hospital, the Putney Hospital, and the Hospital for Nervous Disease, Maida Vale; Examiner in Obstetrics and Gynecology to the Conjoint Board of England; Late Emden Scholar and Mercers Prizeman, Middlesex Hospital Cancer Research Laboratories, and Hunterian Professor, Royal College of Surgeons of England. Third edition, with 309 illustrations. Philadelphia: P. Blakiston's Son & Co.

THIS edition of Berkeley and Bonney's "Obstetric Practice" will be welcomed by those already familiar with the work and will prove to be an invaluable aid to those to whom it comes as a new treatise. The book does not deal with normal pregnancy and childbirth, but only with their diseases and accidents; this strikes one as peculiar at first, but it is really logical and in analogy with the procedure in regard to other branches of medicine. Pregnancy and childbirth being normal processes, it is proper to consider them separately for the same reason that physiology and pathology receive separate treatment.

None of the difficulties of the subject is omitted, the

book beginning with the difficulties of diagnosis of pregnancy and ending with the diseases and injuries of the newborn child. In this edition a supplementary chapter on the feeding of infants has been contributed by Dr. H. C. Cameron. This subject might appear not to be in keeping with the plan of the book to deal only with abnormalities, but it really is, for the only normal infant feeding is breast feeding, and artificial feeding may in all truth be called difficult.

The book is written in an easy style, and the lucid descriptions in the text are made still more clear by many excellent illustrations. It is not to be recommended to the student until he is thoroughly familiar with the physiology and mechanism of normal pregnancy and labor and their management by watchful waiting but then, before beginning his accoucheur apprenticeship, he will find this work of the greatest value, and a general familiarity with its teachings will give him confidence to take the oversight of his early cases of midwifery.

GYNÄKOLOGISCHES VADEMECUM für Studierende und Aerzte. Von Prof. Dr. A. DÜHRSEK in Berlin. Dreizehnte und vierzehnte verbesserte Auflage. Berlin: S. Karger, 1920.

THIS work first appeared in 1891. The ninth-tenth edition followed in 1913, having been the occasion of important addenda. The present edition—thirteenth-fourteenth—has also been improved in accordance with the scientific developments of the intervening years.

INTRODUCTION TO GENERAL CHEMISTRY. An Exposition of the Principles of Modern Chemistry. By H. COPAUX, Professor of Mineral Chemistry at the School of Industrial Physics and Chemistry of the City of Paris. Translated by HENRY LEFFMANN, A.M., M.D., Member of the American Chemical Society and of the (British) Society of Public Analysts. Philadelphia: P. Blakiston's Son & Co., 1920.

THIS little book is the result of an effort so to present the fundamental principles upon which the modern science of chemistry is founded that they will be readily comprehensible and that the student will absorb them in a form that is substantially correct. The author has been singularly successful in his task and his translator has performed his duty well. The book should be welcomed by junior students of chemistry and is one that senior students and even practising chemists would do well to read so that their ideas (often erroneous) may be clarified and corrected.

THE SYSTEMATIC TREATMENT OF GONORRHOEA IN THE MALE. By NORMAN LUMB, O.B.E. (Author of "The Urethroscope in the Diagnosis and Treatment of Urethritis"), Late R.A.M.C. Specialist in Venereal Diseases, and Officer-in-Charge of Divisions 39 and 51 General Hospitals, B.E.F.; Clinical Assistant, St. Peter's Hospital for Stone. Second Edition. Philadelphia and New York: Lea & Febiger, 1920.

THIS little volume is intended as an aid to the general practitioner. The author lightly touches upon the essentials of etiology, pathology, diagnosis, and treatment of gonorrhea and its complications. He wastes time and space in the consideration of such worthless procedures as electrothermal therapy and intramuscular administration of colloidal preparations of palladium and manganese. Because of his results with detoxicated vaccines he is optimistic toward this type of therapy. Occasional ambiguities mar the general clarity of expression of his thoughts.

HANDBUCH DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE. Herausgegeben von Dr. L. KATZ, Spezialarzt für Ohren, Nasen, und Halskrankheiten in Ludwigshafen a. Rh.; und Prof. Dr. F. BLUMENFELD, Arzt für Nasen, Hals, und Lungenkrankheiten in Wiesbaden. Vol. II, No. 6. Leipzig: Verlag von Curt Kabitzsch, 1920.

THE present installment of 188 pages comprises an article on the surgical diseases of the internal ear by Prof. W. Uffenorde of Göttingen, who in a succinct and comprehensive manner discusses this subject under the following headings: inflammatory diseases, wounds, tumors, and malformations; and functional indications of surgical intervention. A series of fourteen colored plates accompany this number.

SECTION ON MEDICINE.

Stated Meeting, Held February 15, 1921.

Dr. SAMUEL BRADBURY in the Chair.

The program of the evening was presented by the Staff of Montefiore Home and Hospital.

Diagnosis of Intrathoracic Neoplasms.—Dr. MAURICE FISHBERG read this paper. (See page 513.)

Dr. DOUGLASS SYMMERS stated that from the anatomical standpoint, intrathoracic tumors, exclusive of the teratomata, were divisible, broadly, into three groups; namely, those springing from the thymus body or its remnants, those from the peribronchial lymph nodes and those from the lung proper, including the bronchi, the interstitial tissues, and the pleura. Tumors springing from the thymus formed an interesting group. For example, there was a variety of thymic lymphosarcoma which grew expansively and was apt to produce mechanical symptoms referable to the upper mediastinum. It was interesting to observe that lymphosarcomata of this description sometimes caused bilateral enlargement of the kidneys due to extensive infiltration of tumor cells. In two cases of this description encountered at Bellevue Hospital, the combined weight of the kidneys was 1040 and 1100 grams, respectively. In some cases lymphosarcomata of the thymic remains were richly vascularized, so that the tumor might actually pulsate, giving rise to symptoms that suggested aneurysm. A certain proportion of all cases of myasthenia gravis was associated with lymphosarcoma of the thymus. Still another form of lymphosarcoma of the thymus which was extremely important from the standpoint of recognition, was the so-called leucosarcoma of Sternberg. It grew for a period of months or years as an ordinary lymphosarcoma, and then suddenly commenced to pour lymphocytes into the blood, terminating life with the symptoms of acute leucemia. Finally, there was a variety of enlargement of the thymus body which presented the histological characteristics of Hodgkin's disease. In one such case observed by Dr. Symmers, the sternum was extensively eroded and in another case the growth penetrated the suprasternal region, replacing a portion of the thyroid gland. This latter case was associated with extensive edema of the upper part of the chest and of the right arm. There was still another variety of thymic tumor, the exact nature of which was at present unknown. Dr. Symmers stated that in 1914 he and Dr. Morgan Vance had observed a tumor of the thymic region that was roughly triangular in outline, measured 18 x 25 cm., and produced extensive nodular metastatic deposits in the lungs and pleura and in the vertebrae, from whence it infiltrated the spinal cord with the production of complete paraplegia. The patient showed no respiratory symptoms referable to the presence of the growth. Dr. Symmers said that the histology of this growth suggested the possibility of origin from Hassell's bodies. The second group of intrathoracic tumors was represented by the lymphosarcomata of the peribronchial lymph nodes. This type of growth was more apt to mould itself around the vascular and other tubular structures of the part, compressing them rather than producing direct infiltration. It tended, however, to spread along the peribronchial connective tissues. Finally, there was a group of tumors springing from the tissues of the lung itself. In the past eighteen months Dr. Symmers stated that he had seen seven cases in which the diagnosis of primary tumor of the lung could be made with reasonable, if not absolute, certainty. Primary tumors of the lung were not to be diagnosed anatomically until every possible source for the origin of metastases had been eliminated. Metastasis might come from minute diverticula of the esophagus that had undergone epitheliomatous transformation with secondary involvement of the lungs. Of seven primary lung tumors encountered at Bellevue Hospital, one was an epithelioma of the bronchus, three were adenocarcinomata springing from the submucous glands in the bronchi, two mesotheliomata of the pleura, and one spindle-cell sarcoma.

Dr. SIDNEY YANKAUER called attention to the fact that Dr. Fishberg had failed to make mention of the bronchoscope, and emphasized the importance of this method of examination. In the last four years he had examined about 100 cases of pulmonary suppuration of various kinds in patients of different ages. In 16 instances a tumor was definitely diagnosed with the bronchoscope. From the standpoint of the bronchoscopist there were two kinds of intrathoracic tumors. One grew externally to the bronchi and made itself evident only by the fact that it pressed upon a bronchus. In these cases the nature of a growth could not be determined because the growth could not be seen. In another class it either originated in or broke its way into the bronchus and in such cases the bronchoscope was of great value. One could remove a piece of the tumor and make a microscopic examination. Of the 16 intrabronchial tumors ten were carcinoma and three sarcoma; of which two occurred in children and one in an adult. The other three cases were benign tumors which had not been mentioned this evening, namely, two fibromata and one granuloma. The fibromata were both removed with the bronchoscope and in both cases a complete cure was effected. The great value of the bronchoscope lay in the possibility of a definite diagnosis, and of a diagnosis when the tumor was small enough to be suitable for removal. He believed that the thoracic surgeon would not hesitate to enter the chest and remove a tumor at the stage at which it could now be discovered.

Dr. MORRIS MANGES said that Dr. Fishberg's paper showed what could be done by the study of physical signs if one started out to make a diagnosis by physical signs. He felt that we were leaning too hard upon the x-ray and that many had forgotten the value of a careful physical examination. He was very glad Dr. Fishberg had not brought his x-ray illustrations for without them he had been able to bring this lesson home much better.

Dr. ALFRED MEYER stated that Dr. Lilienthal had been called out and before going had asked him to accentuate that occasionally artificial pneumothorax was of value in diagnosis if the chest was first aspirated and then an x-ray plate taken. Then he himself also wished to accentuate that one should not become too enthusiastic over one method and decry other methods but should use every link in the chain in trying to forge a diagnosis. From his own point of view, Dr. Meyer said he wanted to say a word as to the value of cytology. If there was only pulmonary involvement with the pleural effusion due to mechanical cause simply and not to involvement of the pleura the likelihood was that one would get little information by tapping, but in many cases there was secondary involvement of the pleura and the chances of confirming the diagnosis by tapping and cytological examination were more favorable than Dr. Fishberg had said. It depended upon the kind of examination that was made. Dr. Mandelbaum had developed a method of cytological examination of tapped fluids which had helped him in malignant disease of the lungs and pleura and in intraabdominal disease supposedly malignant. One could collect the fluid in a sterile bottle, centrifuge it, imbibe the sediment in paraffin, cut sections, stain and mount. Dr. Meyer stated that he had personal knowledge that that method was not followed very extensively and he would like to suggest its wider use, and hoped that other laboratories would go into the finess of the method in order that they might have a larger percentage of positive results.

Dr. A. S. BLUMGARTEN spoke of the value of pneumothorax as a diagnostic aid. They had been using this procedure for two years at the Lenox Hill Hospital. One patient had had repeated pleural effusions for fourteen months, and the physical signs and x-ray photographs showed nothing but pleural effusion though a large number of x-ray plates had been made. Finally the fluid was withdrawn and the pleural cavity inflated with oxygen and then a mass about the size of a walnut was revealed in the x-ray pictures. Consequently they were very sure this was a primary tumor of the right lobe. The right lower lobe of the lung was removed and the patient recovered; he died eight months later of chronic nephritis. Strangely enough when the pathologist's report came back it stated that

the tumor was benign. Artificial pneumothorax with oxygen and an x-ray had shown the mass when all other methods had failed.

Dr. FISHBERG, in closing the discussion, said he had an antipathy for any one who urgently claimed priority, but nevertheless he would like to go on record that this system of artificial pneumothorax for the diagnosis of tumor of the lung had been evolved at the Montefiore Home during the past three years. This was brought out in an article that had been sent to the *Journal of the American Medical Association* two months ago and would soon be published. He was not saying this for the purpose of establishing priority but to record the actual fact. Now, as to what Dr. Symmers had said, he felt very grateful to him for his elucidation of the pathology which he himself did not feel competent to discuss. He was much gratified to hear him say that during autopsy it was at times difficult to differentiate primary and secondary tumors of the lung. The question might be asked how they knew that the tumors he had reported were all primary. But if a pathologist, while making an autopsy, could not decide, how could the poor clinician who was merely a practitioner of the art of medicine be able to decide? However, he considered lung tumors primary when no metastatic deposit could be found in any other part of the body. As for the cytological examination, they had been getting the fluid, centrifuging, cutting sections, staining, and making examinations, and the pathologist could not always say that they were dealing with tumor cells. The cytological examination had often shown epithelial cells, and cells looking like cancer, but one could not place as much confidence on such a finding as upon finding a pneumococcus or tubercle bacilli. As for the bronchoscope, he had had no experience. As a tumor invaded the lumen of a bronchus in only perhaps 10 per cent. of the cases there would be 80 or 90 per cent. in which the bronchoscope would not reveal what could be found by physical signs.

Clinical Aspects of Disturbance of Cardiac Conductivity.—Dr. B. S. OPPENHEIMER made this presentation. He stated that the electrocardiograph did not give direct evidence of the muscular condition of the heart; it did, however, show disturbances in conductivity. It had been learned that auricular flutter, impure flutter and fibrillation were really due to disturbances in conduction within the auricle. Lewis had recently produced auricular flutter in dogs by increasing the heart rate. Auricular fibrillation, instead of being originated by multiple foci, was found to originate from a single point. Dr. Oppenheimer showed by means of lantern slides and charts that the excitation wave travelled in a circle and when the rate was sufficiently increased the successive excitation waves interfered with one another causing block in certain areas. Clinically extrasystoles did not diminish the output of the heart. In auricular flutter the output of the heart was diminished 15 per cent. and the blood pressure was reduced 15 per cent. This was in part due to the abnormal increase in the ventricular rate. In auricular fibrillation the output was reduced 40.6 per cent.; the blood pressure 34.8 per cent. In heart block the output might be reduced 44 per cent. and the blood pressure 33 per cent. In complete heart block the output was reduced 60 per cent. It therefore appeared that to determine the efficiency of the human heart one should study its muscular conductivity.

Dr. ROBERT H. HALSEY stated that as the various forms of interference with conduction of impulses from auricle to ventricle had been described and illustrated very beautifully, he would show some electrocardiograms of ventricular tachycardia with complete block instead of duplicating what Dr. Oppenheimer had said. The first slide illustrated auricular flutter with a ventricular rate of 150 and an auricular rate of 300—that is to say, there was a two to one block. Individuals with this type of tachycardia frequently responded promptly to digitalis therapy and sometimes, as in this case, had a return of normal sequential rhythm under the normal pacemaker. The next slide, taken while the patient had been lying quiet, showed the ventricle beating at 165, while the auricle contracted only 75 times per minute. After exercising, the record showed the ventricle maintained its high rate while the auricle increased to 105. This showed

that exercise affected the auricular rate but not the ventricular which was of intraventricular origin and there was complete block without retrograde impulses to auricle from ventricle. Without such aid as the electrocardiograph, it would be impossible to elucidate such conduction difficulties as shown.

Dr. SELMAN NEUFHOF spoke of sinoauricular heart block. He said that while this condition was usually due to digitalis, he had seen at least two instances in which it was due to tobacco poisoning. The theory of Garrey and Mines was very fascinating, but he wondered how, after all, their theory of "inter-auricular block" accounted for the clinical and autopsy conditions in which auricular fibrillation was so common. He thought there were possibly mechanical changes in auricular texture, such as the thickening found in cardiosclerosis, or the auricular distention and dilatation found in mitral stenosis which might act as mechanical factors in preventing the normal spread of the auricular impulse, thus tending to block the impulse and hence cause auricular fibrillation. Of course those having auricular fibrillation were usually at a tremendous disadvantage from the circulatory standpoint; yet one saw patients aged seventy and more getting along fairly well; usually a pulse deficit was absent in these individuals. This led one to speculate as to the reason for the comparative absence of symptoms. It might be because the progress of the myocardial disease had been a gradual one, thus gradually allowing the heart to make up for the deficiency. Besides, these elderly people were not subjected to great circulatory strains. At any rate it was a fact that many subjects of auricular fibrillation grew to be old people.

Dr. CARY EGGLESTON mentioned a point which had interested him not only in relation to Dr. Oppenheimer's paper but before, that was with reference to Eyster's figures. Eyster's figures gave one the impression that partial heart block was a condition of greater clinical severity than auricular fibrillation so far as subjective symptoms were concerned. He did not wish to be understood as saying that the figures were wrong, for they were doubtless correct for animals, but from the clinical standpoint they conveyed a wrong impression. Fibrillation was symptomatically a far graver condition than partial heart block, though not prognostically as grave.

Dr. LOUIS FAUGERES BISHOP stated that one of the most important points was that of compensation and in heart block they had an example of what compensation would do in these old people who stood fibrillation and stood it well; it was because they had developed a certain amount of compensatory heart block. He had at the present time under observation three persons with large old rheumatic hearts with chronic fibrillation. All of them had developed partial heart block and they went along fairly well month after month without digitalis because the rheumatic lesion had not only produced fibrillation but also a fairly complete heart block. He thought that the idea that heart block might be beneficial in many cases of fibrillation was of great interest. Dr. Oppenheimer's paper was extremely interesting and satisfactory as we were all very much puzzled by these intermediate cases where we did not know whether we were dealing with a fibrillation or a flutter. Dr. Bishop cited one instance which he had just seen in which the first part of the electrocardiogram showed a flutter and then in the second half it went into a fibrillation. It was very puzzling in some cases to decide whether one was dealing with flutter or fibrillation; in these cases he was apt to consider the condition one of fibrillation but they offered an interesting debating ground.

Dr. HAROLD E. B. PARDEE said that he was glad to have this new conception of auricular fibrillation made more generally known, because the old theory of multiple foci of extrasystoles had not been satisfactory. This new theory of Lewis' explained many things both clinical and experimental, that could not be explained by the old theory. There was one thing mentioned by Dr. Oppenheimer which would be found very helpful in the diagnosis of auricular flutter when an electrocardiographic record was not available. This was the slowing of the pulse rate which resulted from pressure upon the vagus nerve in the neck. The heart

slowed with pressure and quickly speeded up again when it was stopped reaching exactly its former rate. Such an effect from vagus pressure could not be obtained when the heart was rapid with a normal A-V mechanism, nor when it was rapid because of paroxysmal tachycardia. The slowing with flutter was due to the effect of vagus pressure in diminishing the function of conduction between auricles and ventricles. The same phenomenon of slowing would be produced if auricular fibrillation were present with rapid rate, but he thought that this could usually be distinguished from auricular flutter by the irregularity. Eyster's figures showed the comparative efficiency of the circulation during normal slow rhythm and during the abnormally rapid rate when auricular flutter or auricular fibrillation was experimentally induced. The situation was nothing like that which we met clinically, for in clinical auricular fibrillation the ventricles were always kept slowed, or at least should be, by the action of digitalis. He felt that incomplete heart block, a two to one block, was more serious than auricular fibrillation because in the latter condition the danger was from a too rapid ventricular rate, and this danger could be easily controlled by digitalis. We must not be over-impressed with the relative unimportance of extrasystoles, though considering only their effect upon the efficiency of the circulation; we must consider also their importance as a sign of myocardial disease. This brought up the question of the value of the auricle in the efficiency of the circulation. Henderson's work had shown that the auricle had little or no effect in driving the blood, its chief function apparently being to bring about a proper closure of the flaps of the auriculoventricular valves. Moreover, it was hard theoretically to understand how a very brief pressure rise of only about 10 mm. of mercury, taking place at the side of the ventricles opposite to the aorta, could have much effect upon the circulation as a whole.

Dr. OPPENHEIMER, in closing the discussion, said that Dr. Halsey's cases were very remarkable in showing all the different conduction disturbances. As to the prognosis in these conduction disturbances a great deal depended upon the complications that might be present. According to the estimations made by Eyster and Swartwout the normal heart of the human being could do ten times as much work as it was ordinarily called upon to do. If its efficiency were reduced by 40 per cent. it would still have a tremendous factor of safety. That was the reason Dr. Neuhoef had seen auricular fibrillation run along for years. The prognosis was not dependent upon the heart block, but usually these patients had some unusual underlying condition that determined the prognosis. They hoped in a few months to be in better position to give some idea of the outlook in cases of heart block. As regards the action of the auricles, Henderson thought that they had little effect on the circulation, but if one read Starling's work it would be found that he considered diastole as important as systole in its effect on the output.

Delayed Resolution in Lobar Pneumonia.—Dr. HARLOW BROOKS presented this paper, in which he stated that the subject, delayed resolution in lobar pneumonia, received relatively little attention in most textbooks, and for the greater part it was mentioned, when at all, as of infrequent occurrence and apparently of little clinical importance. It was probable that it was much more frequent than casual statistics would indicate, for the reason that many practitioners both in and outside of the hospital were accustomed to discharge their pneumonia cases long before all the physical signs of pulmonary infiltration had disappeared from the lungs, and in more than a few instances he did not exact final searching reexaminations. His experience in the military service, during which period he was enabled to follow his cases for much longer periods than was usually customary in civil life, had convinced him that the condition was far more frequent than he had supposed and its importance was much greater than was usually accepted to be the case. Its occurrence differed greatly in different seasons and particularly in the various epidemic types of pneumonia. No definite period could be fixed as to when all the signs of pneumonia should disappear from the lung under normal conditions, and the term "delayed resolution" was

therefore a very elastic one and in large degree inaccurate. For clinical purposes perhaps one was justified in assuming that, when definite progress in resolution occurred after a period of improvement, but then the exudate failed to resorb with a rapidity discernible from day to day, one was then dealing with a delayed resolution. One must not group as delayed resolution those instances of pneumonia in which an interstitial pneumonia followed the acute disease, nor yet those cases in which pulmonary gangrene or pulmonary abscess occurred. If one accepted the definition proposed it would be found, he believed, that most cases of delayed resolution presented no elevation of temperature after the subsidence of the acute course; if, however, one included those instances in which abscess or pulmonary gangrene or pulmonary fibrosis occurred, it would be found that an elevation of temperature did persist. Most writers made the statement that delayed resolution occurred chiefly in the asthenic, the debilitated, and in highly intoxicated cases of pneumonia. If we included under this title cases which developed pulmonary abscess or pulmonary gangrene, this was beyond doubt a correct assumption, but if we accepted the classification which he proposed, he did not think we could accept this statement, for the cases in which he had particularly observed the conditions the subsequent complete resorption had not been of this character. The statement was also generally accepted, and was so stated in most textbooks, that delayed resolution occurred most commonly in the lower lobes. The experience of the war pneumonias was rather the persistence of foci of infiltration in the upper lobes, hence the frequency of the mistaken diagnosis of pulmonary tuberculosis. He did not feel that we were as yet justified in any very definite conclusions as to the causative factors back of delayed resolution in pneumonia. There could be no doubt, however, but that hypostasis from monotonous position, from a defective heart action, or from a frank septicemia, favored delay in resolution. The most important phases of differential diagnosis lay in most instances between developing pulmonary abscess, pulmonary gangrene, atelectasis, pleural effusions, thickened pleura, pulmonary fibrosis, and neoplasms. The differentiation of delayed resolution from pulmonary abscess and gangrene was relatively easy: from the temperature course which sooner or later in the latter conditions assumed a septic course, from the x-ray findings, from an increasing evidence of necrosis, and with absolute conclusiveness from the character of the sputum which eventually declares itself. The differentiation from atelectasis as from pulmonary embolism was much more difficult. The history of an embolism, the x-ray or fluoroscopic appearance with a falling away of the involved tissue from the pleural wall were all usually sufficiently decisive to admit of satisfactory differentiation. Thickened pleura, if it was accompanied with an organized exudate and with pleural adhesions, was by no means easy of differentiation, and final separation could perhaps be determined only by the course, namely, when the beginning of resorption was evident on the one hand and absent on the other. Where pleural effusion or pleural thickening or organization was associated with delayed resolution, differentiation by auscultatory and tactile fromitis, and by other physical signs, was by no means simple, and repeated observations were commonly necessary. Pleural effusions were more frequently confused with delayed resolution than any other one condition, particularly when the exudate was, or was supposed to be, interlobar or encysted. The x-ray would materially help in some instances, but in others it confused rather than otherwise, and the more definite method appeared to be the precise location of the shadow with the x-ray or fluoroscope, and the differentiation finally by diagnostic needling, oftentimes frequently repeated. The diagnosis from tuberculosis was particularly difficult, though in many, perhaps most, instances the greater frequency of the delayed resolution in the basal portions of the lung tissue, and the greater frequency of tuberculosis in the upper portions of the lung were helpful. As a rule, the shadow or area of dullness in delayed resolution was larger and more dense than was the case in the earlier phases of pulmonary tuberculosis, and the gradual tendency of the delayed resolution to clear, first at its periphery, while tuberculosis necrosed

centrally or became more dense, were also points of great assistance. Finally, loss in weight, increasing fever, augmenting asthenia, and the finding of tubercle bacilli furnished means of differentiation. Pulmonary fibrosis could oftentimes be differentiated by the ultimate result, and one could never be sure but that the area of supposed delayed resolution might not be undergoing fibrosis. It must be recalled that in many instances probably a pulmonary fibrosis succeeded a delayed resolution. Pulmonary neoplasm was most frequently first diagnosed as probable pulmonary fibrosis, or if associated with the history of an acute pulmonary inflammation with delayed resolution. The asthenia, cachexia, progressive anemia, etc., which characterized so many neoplasms even in their very early stages were largely wanting in many new growths of the lungs. The spread of the neoplasm, contrasted with the stationary character or retrogression of delayed resolution, were two points of differentiation of particular value in which the fluoroscope or plate were of even more conclusive value than physical examination. Sharp lines of limitation, unless at the lung borders or the bronchial septa, indicated neoplasm as a rule; for generally delayed resolution presented lines of limitation of a less definite and more hazy character. Where the pleural surfaces were involved, thoracotomy with the removal of a fragment of pleural tissue for biopsy was justified. An important point of differentiation between pulmonary neoplasm and delayed resolution was the relatively early appearance of circulatory deficiencies or of dyspnea in cases of neoplasm; these two symptoms were strikingly small in delayed resolution, even when it was of quite wide distribution. The involvement of lymph nodes in the mediastinum was almost certain to be present in both conditions. The differentiation of these two conditions was extremely difficult.

Dr. C. N. B. CAMAC, after congratulating Dr. Brooks and the Section on the paper, stated that the subject was one which was very difficult at the moment to discuss, because during the past few years the term pneumonia had taken on so much more specific an application. It must be stated definitely whether one was speaking of a pneumococcus or of an influenza pneumonia, or any of the other bacterial pneumonias, and also whether one was speaking of lobar or bronchial pneumonia. He did not believe we could accept the diagnosis of unresolved pneumonia until we knew with which of the pneumonias we were dealing. The work of Dr. Cecil on experimental pneumonia in the monkey presented the subject in an entirely new aspect. In only one instance in this experimental work on monkeys inoculated intratracheally with pneumococcus did they find an unresolved pneumonia. Dr. Camac quoted from Dr. Cecil's report (*Journal of Experimental Medicine*, April 1, 1920, xxxi, 4, p. 421) commenting on this instance of unresolved pneumonia following prolonged illness to show that the writer used the term unresolved pneumonia very guardedly. In speaking of pneumococcus pneumonia we again had to take into consideration the various subdivisions, so that we could not speak of this infection as broadly as we formerly did. Another point that entered into the question was that, in studying the mechanism of recovery from pneumonia it seemed that we must consider both that of the local condition in the lungs and that of the system. To make this clear, Dr. Camac again quoted from the report of Dr. Cecil and Dr. Blake, as follows: "The mechanism of recovery from lobar pneumonia has been the subject of much investigation. Neufeld and Haendel, Cole and his coworkers, Blake and others, have attributed it in part to the development of humoral antibodies and have demonstrated the appearance of these antibodies in the circulating blood at or about the time of crisis."

Lord has suggested that another factor may be of considerable importance in bringing about crisis and resolution of the pneumococcal process, attributing recovery to local biochemical changes in the course of which the acid death-point of the pneumococcus is reached.

In one instance crisis with recovery occurred with pneumococcus septicemia persisting forty-eight hours after crisis. In several instances a critical fall in temperature has occurred about the seventh or ninth day with subsequent return of fever and death several days later. Autopsy has shown a resolving pneumonia, death apparently being due to a persisting pneumo-

coccus septicemia usually associated with some complication." Dr. Camac called attention to the fact that the pathology in the involvement in a pneumococcus pneumonia was a surface one; the deeper tissues were not attacked; whereas in an influenza and streptococcal pneumonia the deeper tissues were attacked, so that one found an entirely different process to consider pathologically as well as bacteriologically. When unresolved pneumonia was considered, it should be accepted as a diagnosis with caution because one might be led to overlook some complication of serious moment, but amenable to treatment. It was well known that physical signs were often present long after the acute stage of a pneumococcus lobar pneumonia, and frequently the individual went on to recovery with signs still present, but it was a most misleading conclusion to draw that these cases with continued symptoms and signs had unresolved pneumonia. In 139 cases of pneumococcus lobar pneumonia among soldiers he had seen no cases of delayed resolution; with persistent search complications were always found to explain the continued fever or other symptoms. Bronchopneumonia presented an entirely different problem, and any pneumonia in children or in old people was still different. It might be that in old people and young children and those exhausted by long illness we were dealing with biochemical changes influencing resolution. In this connection it was noteworthy that Dr. Brooks had stated that most of his cases of delayed resolution were bronchopneumonia. Dr. Camac said he felt that to deal with this subject in greater detail would go beyond the limits of a discussion, but stated that while he was not willing to say that delayed resolution in pneumococcus lobar pneumonia never occurred, yet he thought it to be extremely rare and that it should be accepted as a diagnosis only when every other complication had been positively excluded. On the other hand, bronchopneumonias of the influenza or streptococcal bacteriology, or any pneumonia in the extremes of life or in those depleted by disease or undernourishment, might fail in the reparative process. He expressed the hope that when Dr. Brooks published his paper from his large number of carefully observed cases he would state specifically the bacteriology and pathology of the unresolved cases. Dr. Camac believed we were as yet far from a clear understanding of just what was meant by "delayed resolution" and "unresolved pneumonia" in spite of the brilliant advances made by research in the pathology and bacteriology of pneumonia.

Dr. RUSSELL L. CECIL stated that the studies on pneumonia to which Dr. Camac had referred had been carried out at the United States Army Medical School in Washington and had been published in the *Journal of Experimental Medicine*. It was interesting to see in monkeys with pneumonia how advanced the process was in many instances some time after the monkey had recovered. In the animals that had recovered it was found that the process of resolution was still going on. If we had a way of obtaining lung tissue from convalescent pneumonia patients we would be amazed to see how many tissue changes remained long after the pneumococcus had been killed.

Dr. FISHER said he believed that at the Montefiore Home they had had opportunities to study certain chronic pulmonary processes which were new in the United States among the native population. In the textbooks it was stated that bronchiectasis was a very rare disease, which was true in the native population, but at the Montefiore Home they were getting people from a portion of the world where the influenza has been endemic for many years, and they were finding localized pulmonary processes resulting from these infections. He had recently seen such conditions develop in New York after the new epidemic. If following an acute attack of pneumonia the temperature did not come down, the first thought should be of localized empyema or pulmonary abscess. That abscess might be a large one and cause trouble, or perhaps kill the patient, but there might be many small abscesses, such as Dr. Symmers had found while making autopsies and described in the *A. M. A. Journal* two years ago. These small abscesses might break into a bronchus. Usually they were localized in the left lower lobe, rarely in the right, and rarer still in the upper lobes.

In those who survive the acute stage, fibrosis was going on with resulting dilatation of the bronchi. These cases were quite easy to diagnose immediately after pneumonia; if the pneumonia did not resolve, the chances were eight out of ten that one was dealing with a localized empyema or an abscess formation in that particular area. Dr. Fishberg said he was glad to hear what Dr. Camac had said. In the true old-fashioned pneumonia resolution occurred very quickly. It was only after the bronchopneumonia of influenza, or the various types of streptococcus pneumonias, not commonly seen previously, that he saw these particular cases in which a small abscess formation occurred and left the patient with a localized suppurating lesion. Patients with these chronic abscesses might go on afebrile and quite comfortably for years, though now and then, when drainage was obstructed, they suffered from an acute exacerbation of the fever, etc., and then a diagnosis of pneumonia was made. The result was that these patients gave a history of several attacks of "pneumonia." He agreed with Dr. Brooks that in chronic cases there was at times great difficulty in differentiating this condition from cancer of the lung. However, a careful consideration of the history, symptomatology, and physical signs, coupled with good radiographic plates, should, in most cases, lead to a proper appreciation of the nature of the disease.

Dr. Brooks, in closing the discussion, said he thought Dr. Camac had failed to get his point. He had wished to make clear that he only regarded as cases of delayed resolution those in which there was a definite progress in resolution after a period of improvement; then there would be persistent signs with an afebrile delay. Where there was fever there would be found probably pulmonary abscess or gangrene, especially if a fluoroscopic examination was made. These cases occurred in lobar pneumonia, but more frequently in bronchopneumonia. Dr. Manges had asked with reference to the treatment of these cases with the x-ray. It was their idea that some of these cases improved as a result of the frequent fluoroscopic examinations to which they were subjected.

The Right Ventricle in Pulmonary Tuberculosis.—Dr. E. P. BOAS read this paper, in which he reviewed briefly the literature bearing on his subject. He stated that it seemed that many had believed that possibly with increased fibrosis in the lung dilatation and hypertrophy would occur in the right heart, and that if there were adhesions impairing the elasticity of the lung the effect on the pulmonary vessels might be similar to that of arteriosclerosis and would increase the work placed upon the right heart. A number of authorities had reported that right ventricular hypertrophy occurred with lung adhesions. However, in most of these reports the method of determining the hypertrophy of the heart were not accurate. The present investigation was undertaken to determine by means of the electrocardiograph what the influence of fibroid phthisis was upon the ventricles of the heart. The investigation included 97 patients in whom a careful history and a thorough physical examination was made, special attention being paid to the cardiovascular condition. Electrocardiograms were taken in the usual way and interpreted by Dr. Mann. The results of the investigation did not confirm the views that were quite generally held. Of the 97 cases, 27 showed left ventricular predominance and 29 showed right ventricular predominance, while 41 showed predominance of neither the right nor the left ventricle. It was well known that many cases of hyperthyroidism showed left ventricular predominance, and that symptoms of Graves' disease often occur in the tuberculous. To determine the influence of hyperthyroidism in the presence of tuberculous cases presenting this complication were compared and as many with right as with left ventricular predominance were found. The same was found to be the case in fibroid phthisis and whether the tuberculous was active or inactive. Right ventricular predominance was not associated with any particular type of tuberculous. Three cases showing hyperthyroidism to the same degree and pulmonary lesions practically identical were studied; one showed left ventricular predominance, one right ventricular predominance, and one showed a normal electrocardiogram. Study was also made of the blood pressure and x-ray observations were made,

and these seemed to show no constant finding associated with fibroid phthisis. The duration of the illness seemed to have no influence in determining the condition of the right ventricle. The patients in this series were classified by sex, and it was interesting to note that among 49 males and 48 females left ventricular predominance was twice as frequent in the women as in the men, and right ventricular predominance twice as frequent in the men as in the women.

Dr. EGGLESTON congratulated Dr. Boas on the care with which he had analyzed his findings. They were more or less what he would have expected. The pulmonary vascular tree was notoriously distensible. As Wiggers had shown, very wide changes in the pulmonary capillaries could be compensated for by the remaining open vessels without any extra amount of work being thrown on the right heart. The fact that the electrocardiograph showed predominance of a ventricle did not necessarily spell hypertrophy. It would seem that there was not necessarily any relation between phthisis and the condition of the right side of the heart. This work certainly ought to be pursued much further. Dr. Boas's records were too few to serve as a basis for conclusion, but they pointed to the fact that fibroid phthisis had relatively little significance so far as the size of the chambers of the heart was concerned.

THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Held January 26, 1921.

THE PRESIDENT, DR. GEORGE MORRIS PIERSOL, IN THE CHAIR.

Auricular Fibrillation, the Most Common and Important of Cardiac Arrhythmias.—Dr. ROSS V. PATTERSON of Philadelphia read this paper in which he said that auricular fibrillation, considered from the clinical point of view, was the most important mechanical derangement of the heart. It was the most frequent form of disordered heart action associated with the symptoms and signs of cardiac failure. It belonged to the ultimate sequelae of inflammatory and sclerotic endocarditis and valve lesions, myocardial degeneration, and circulatory stress from various causes; it was often the immediate cause of cardiac failure. Auricular fibrillation occasioned a profound derangement of the normal cardiac mechanism by reason of over dilatation of the auricular walls, fibrous overgrowth, and functional dissociation of the muscular fibers. The auricles no longer acted as efficient contracting chambers, but stood in a position of permanent diastole, acting merely as reservoirs of the blood which reached them from their tributary veins. The general circulatory effect in extreme grades of this disorder was a lowering of arterial pressure with a tendency to its transference to the venous system through the pulmonary circuit. As a result there occurred congestion of the lungs, engorgement of the entire venous system, general visceral congestions and often the outpouring of the fluid portion of the blood into the subcutaneous tissues and serous cavities of the body. Auricular fibrillation, therefore, produced marked disorder of the cardiac contraction, circulatory failure of advanced degree, and, owing to the congestion of the viscera, interference with the function of many organs, the function of the lungs being early and severely affected. In extreme grades the symptoms were those of rupture of compensation—cyanosis, edema, dyspnea, and the usual evidences of interference with the function of the kidneys, stomach, liver, and other organs, a pulse extremely rapid in rate and wholly irregular in character, the beats varying as to both sequence and force. Palpation and auscultation at the apex revealed the disorder of the ventricular action. The heart beat as compared with the pulse beat might show a difference of as many as 30 or 40 or more per minute. The outlook was dependent, not only upon our ability to control the ventricle, but also upon the degree of damage which it had suffered as a result of the influence of causes which had also affected the auricle and perhaps the arteries and other organs as well. Like other cardiac conditions the prognosis was largely a myocardial

question, due importance being accorded to the mechanical and dynamic considerations affecting the heart, blood vessels, and their contents. The effects of treatment were often brilliant. There was no condition in which a physician might so easily gain a reputation if he would but familiarize himself with the principle of treatment and administer remedies with persistent determination. The ordinary treatment for the restoration of the circulatory balance by rest, purges, venesection, and the treatment of special symptoms due to visceral congestion should be utilized. Digitalis or an allied drug should be administered in every case in which, while the patient was at rest, the heart beat exceeded 100 per minute. As soon as reduction to this rate was accomplished the use of digitalis should either be discontinued or greatly lessened in amount. In cases in which the disorder was extreme and the indications were to bring the heart under control quickly an initial dose of one drachm of the tincture might be given followed by an equal amount in each 24 hours divided into 3 or four doses. The rest period in bed should be prolonged beyond the relief of symptoms in order that the overworked ventricular myocardium might gain its tone and the functions of other organs be restored.

Dr. E. B. KRUMBHAR of Philadelphia said that in spite of the commonness and importance of auricular fibrillation we knew little of its actual causation. Though easily recognizable and known to be found in several well defined clinical conditions, its actual pathogenesis was still unknown. Similarly its finer pathology was still obscure and he thought there was an important field for more intensive study of the subject. As to prognosis he thought it was correct that the auricular fibrillation of cardiac sclerosis was a graver condition and less responsive to digitalis than was the fibrillation of rheumatic cardiac disease. Statistics of the duration of life of fibrillators usually limited them to two or three years, but, of course, it was well known that individual patients might live much longer. For instance, in his own family one individual was pursuing a comfortable existence with a fibrillation of more than 12 years duration and his brother had a fibrillating heart for probably more than 25 years. The heart that was not enlarged and beat slowly would probably last longer than the quick heart with frequent rate. As to digitalis, the assay of the leaves used should be known. It was generally accepted that digitalis helped the ventricle, not only by blocking some of the forms of auricular impulses, but also by depressing the irritability of the ventricular musculature. It had been observed that transient attacks of even the graver forms of arrhythmia were by no means uncommon; in fact, transient fibrillation could be divided thus: (1) The single transient attack, occurring in the course of an acute infection or intoxication; (2) The paroxysmal type, often occurring at frequent intervals and clinically bearing some resemblance to attacks of flutter and paroxysmal attacks of tachycardia.

A General Description of Cardiac Arrhythmias.—Dr. LOUIS FAUGERES BISHOP of New York City read this paper in which he said that modern cardiology dated back only 15 years and that it was only about 10 years since the profession had become conscious of its existence. The details of it were quite intricate and baffling, but of vital importance to the intelligent care of those suffering from heart trouble. Many physicians had not taken up the subject at all but had passed it over as a laboratory matter. This was very unfortunate as there was nothing more vital in the problem of the prolongation of life. He said that there were seven varieties of irregular heart and a friend of his had suggested taking, as a way of remembering, the words ships, leaving out the i and putting three A's after it, thus having the letters SHPSAAA. S stood for sinus arrhythmia; H, for heart block; P, for premature contraction; S, for simple paroxysmal tachycardia; A, for auricular flutter; A, for auricular fibrillation; A, for alternation in pulse. In sinus arrhythmia we found the beats of the heart all right in themselves but the intervals between them were unequal, the spacing between the beats becoming gradually broader, then gradually shorter. In heart block we found either a lengthened distance between the auricle and ventricle or no regular interval at all. The former meant that the

impulse of the heart was delayed between the auricle and the ventricle; the other that the auricle and ventricle were beating independently of each other. In premature contractions the ventricle contracted prematurely independently of the rest of the heart. In simple paroxysmal tachycardia the beats were very numerous and crowded together. In auricular flutter the auricle was beating very rapidly and producing small waves at regular intervals, but the ventricle was responding to only a certain proportion of the auricular beat. Often the rate of the auricle was 300 and that of the ventricle 150. In auricular fibrillation the auricle was paralyzed but trembling, and, instead of one definite wave, we had a lot of irregular small waves that could not be counted. The result was to irritate the ventricle and make it very rapid and irregular. Alternation of the pulse was a condition in which the heart was failing and every alternate beat was reduced in size.

Dr. GEORGE W. NORRIS of Philadelphia said that he thought that of all the advantages of working with the graphic methods the greatest was that they taught us to observe carefully. As a result of this most were agreed that 90 per cent. of all the cardiac conditions met with could be practically diagnosed without graphic means. That left 10 per cent. in which the most expert would be left in doubt as to the exact condition. These had to be deciphered principally by the electrocardiograph. Auricular fibrillation was probably the commonest serious arrhythmia. Next in order came premature contractions. This subject was very complex, but a good knowledge of it could be picked up by concentrated work.

Cardiac Arrhythmias.—Dr. JOSEPH SAILER of Philadelphia read this paper in which he said that he had decided to give a brief clinical description of certain cases which showed various forms of cardiac disturbance. G. C., 56 years of age, suffered with dyspnea and dizziness. The heart was enlarged. There was slight reduplication of the first sound at the apex and slight roughness of the first sound at the base, a moderate degree of renal insufficiency, and marked inequality of the blood pressure in the two arms without any evidence of aneurysm. The condition had slowly grown worse because the patient had persisted in continuing his work. Two electrocardiograms showed extreme left preponderance and arrhythmia, and numerous ventricular contractions. J. H. M., 70 years of age, when first seen eight years ago had an extremely irregular heart coupled with great slowness. The heart and liver had been greatly enlarged and there had been periods of cardiac decompensation associated with dyspnea, cyanosis, edema, and hydrothorax. The electrocardiogram had shown a typical slow flutter with very large auricular waves; the auricular beats had been fairly rhythmic, running over two hundred per minute. There had been all the evidences of mitral disease and toward the end of the patient's life there had been vigorous pulsation of the liver. This patient had been given digitalis from time to time, usually with almost disastrous effect. So far as treatment was concerned there had been numerous occasions of marked decompensation, always relieved by numerous baths and caffeine. The latter had seemed to be almost specific. H. F., 27 years of age, suffered from what she called nervousness with violent palpitation and pain in the cardiac region and dyspnea, occurring about three times a day and lasting about five minutes. The pulse was 144, the heart action was fairly regular, and there was evidence of mitral stenosis. The first lead of the electrocardiogram showed only tachycardia. While the second lead was being taken the patient had some violent trembling, but this subsided and the latter part of this lead was normal. During the third lead only the violent muscular tremors were manifest. Occasional premature contractions were present. I. D. had sharp pain in the left chest, under the scapula; there was marked dyspnea with a sense of pressure upon the chest. The remarkable feature of this tracing was the deep notching of the rising branch of wave R in the third lead and there was evidence of moderate right preponderance. J. M. W. had a tachycardia and evidence of hyperthyroidism. She was extremely emaciated and had suffered various nervous shocks. Hers was a case of temporary auricular flutter. During the intervals there was a tachycardia with perfectly normal complexes; then occurred the

flutter which as usually a two to one rhythm. W. S., 29 years of age, felt well, was athletic, had a diastolic murmur and Corrigan pulse, also a right preponderance. The heart was entirely rhythmical. The reason for the right preponderance in this case, which would lead one to suspect a Flint murmur in spite of the Corrigan pulse, was not clear.

Dr. JAMES TALLEY of Philadelphia said that in respect to auricular flutter he had one patient who had had it for more than seven years. He also had at the hospital a carpenter who had been fibrillating for eight years. As long as the man had a pulse that was not too rapid, and there were no premature beats, showing that his ventricle was not involved and his lungs were clear, he might get along for a long time.

Dr. E. B. KRUMHOLTZ of Philadelphia said that it should be emphasized that if digitalis was used in auricular flutter in the attempt to transform this to fibrillation and thence to normal rhythm, and, if this attempt failed, the digitalis should probably not be continued unless it quickly showed an ability to reduce the ventricular rate. The U wave mentioned by Dr. Sailer in one of his cases probably was due to an impulse from the vena cava. He based this opinion on some animal experience, in which, with both auricle and ventricle at rest, a small contraction was observed in the superior vena cava and recorded as a monophasic wave by the galvanometer. The case with the disappearing P wave might possibly be explained as due to paroxysms of auricular fibrillation, such as he had previously mentioned, and these would not be ruled out even if the ventricular action at these times were regular, if one further assumed that complete block was also present.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

MEDICAL COUNCIL OF CANADA.

Toronto, Winnipeg, and Vancouver, June, 1920.

(Concluded from page 460.)

SURGERY.

1. What symptoms may be produced by hypertrophy of the prostate? Discuss the histological pathology of the condition.
2. What clinical symptoms and physical signs are presented in a recent unilateral dislocation of the lower jaw; describe the anatomical features of the joint involved and indicate the appropriate treatment.
3. Describe the anatomy of femoral hernia and indicate the manner in which you would establish the differential diagnosis between inguinal and femoral hernia.
4. Enumerate the possible causes of acute and chronic intestinal obstruction. What symptoms and physical signs would be produced in obstruction caused by a new growth in the lower part of the sigmoid flexure of the colon. Indicate the probable x-ray findings by the use of barium in such a case.
5. On what physical signs would you establish a diagnosis of cancer of the breast? Enumerate the conditions of the breast with which it may be confused. Discuss the differential diagnosis and the treatment.
6. Concussion of the brain: Discuss this condition under the following heads: (a) Common causes, (b) symptoms and physical signs, (c) pathology, (d) appropriate treatment, (e) prognosis and possible sequelae.

ANSWERS.

SURGERY.

1. *Hypertrophy of the prostate* is very common in patients over fifty-five. The different varieties are: (1) General enlargement of all the tissues; (2) local enlargement, giving rise to definite tumors in the gland, which may be glandular (adenoma) or fibromyomatous. These tumors may project toward the rectum, into the urethra, or up into the bladder. The prostate urethra is always lengthened and distorted, so that micturition is interfered with. If the median lobe is enlarged the

internal urinary meatus is more or less blocked. *Symptoms* begin with frequency of micturition, then some difficulty in the act of micturition, with diminution in the power of projection. Some pain and tenesmus occur later. Secondary changes in the bladder depend on the amount of obstruction. Hypertrophy and sacculation come on, and are followed by atrophy and dilatation. Dilatation of the ureters and hydronephrosis are produced still later. As atrophy of the bladder comes on a certain amount of residual urine remains after each act of micturition. As this increases distention and atony are found with overflow incontinence. Cystitis soon comes on, and may be followed by septic changes in the kidney. The early changes may be unnoticed till overflow incontinence appears. Priapism may occur in the early stages.—(*Aids to Surgery.*)

"*Histologically*, an enlarged prostate consists of an overgrowth of the glandular tissue, sometimes diffuse, more frequently in the form of multiple adenomata, set in a connective-tissue basis developed from the prostatic stroma of muscle fibres. Cystic changes are not unusually observed in these adenomata. Occasionally a few fibromyomata may develop, but they are decidedly uncommon."—(*Rose and Carless' Manual of Surgery.*)

2. *DISLOCATION OF THE LOWER JAW.* "The mechanism of the dislocation is as follows: When the mouth is opened, the condyle of the jaw slips forward on to the eminentia articularis, and it requires very little force to displace it still further into the zygomatic fossa. The inter-articular cartilage follows the condyle, and the attachment of the external pterygoid muscle to that structure and to the bone explains the occurrence of dislocation from muscular action. The displacement may be unilateral or bilateral, more frequently the latter. The mouth remains widely open, the teeth and the jaws being separated by an interval of about an inch. The lower jaw projects unduly, and is fixed, saliva dribbling over the lip; speech and deglutition are impaired, the pronunciation of the labial consonants being especially difficult. A hollow can be detected immediately in front of the tragus, where the condyle is normally lodged, and in front of this hollow the condyle can be felt, being recognized by the slight amount of passive movement still possible. A finger in the mouth may define the coronoid process in an abnormal position beneath the zygoma. When the dislocation is *unilateral*, the symptoms are much less marked. Some amount of movement of the jaw still remains, whilst the chin is displaced towards the sound side.

Treatment. "Reduction is usually easy. All that is needed is to depress the condyle below the level of the eminentia articularis, when the masseter, temporal, and internal pterygoid muscles speedily draw it back into the glenoid cavity. The patient is seated in a chair; the surgeon standing in front protects his thumbs with thick napkins, and introduces them into the mouth, pressing upon the lower molar teeth. Pressure is continued in a downward and backward direction until the condyle is free, and then the chin is raised by the fingers on either side. The jaw is kept at rest for a week or ten days by means of a four-tailed bandage. Anesthesia is occasionally necessary."—(*Rose and Carless' Manual of Surgery.*)

3. *Femoral hernia* leaves the abdomen through the femoral ring and descends into the femoral canal; this canal is funnel-shaped, is about half an inch in length, and ends at the saphenous opening. Femoral hernia is always *acquired*, and has a sac. Its course is first vertical, then forward, then upward over Poupart's ligament. Its coverings, from without inward, are: Skin, superficial fascia, cribriform fascia, crural sheath, septum crurale, subserous tissue, and peritoneum. The neck of the hernia is situated at the femoral ring; to its outer side lies the femoral vein, and to its inner side is Gimbernat's ligament; in front of it is Poupart's ligament, and behind it are the pubis, the Pectineus, and the pubic portion of the fascia lata. In the immediate neighborhood of the femoral ring are: Anteriorly, the communicating branch between the deep epigastric and the obturator arteries; externally, the femoral vein and deep epigastric vessels; superiorly, the spermatic cord (or round ligament) and the deep epigastric vessels.

In *inguinal hernia*: The impulse is felt above Poupart's ligament; the inguinal canal may be filled; the

hernia emerges on the inner side of the pubic spine (above the inner end of Poupert's ligament); and is apt to recur readily after reduction.

In femoral hernia: The impulse is felt below Poupert's ligament; the inguinal canal is empty; the hernia emerges on the outer side of the pubic spine, and does not recur so readily after reduction.

4. *The causes of acute intestinal obstruction are:* Strangulation through apertures, or by means of bands and contracting adhesions; impaction of foreign bodies or feces; internal hernias; the presence of tumors; volvulus or intussusception; intestinal paralysis; disease in the intestinal walls ultimately narrowing the lumen.

The causes of chronic intestinal obstruction are: Foreign bodies, impacted feces, cicatricial bands outside the intestine, compression of the intestine by tumors, stricture or new growths in the intestinal walls.

A new growth in the lower part of the sigmoid flexure would cause at first constipation, rumbling, distress over abdomen but chiefly in left lower quadrant; there would be delay of meal in reaching the rectum and also obstruction to an enema. Later, there might be diarrhea, and if the tumor had ulcerated or broken into the intestinal lumen, blood, or pus might be passed with fecal matter or even independently of it. Examination with a proctoscope might show the tumor, and excision of a piece would show if it was malignant or benign. X-ray findings might be negative, owing to the part of the intestine affected being behind the pelvic bones; but, on the other hand, a combined screen and plate examination, with an opaque enema, may show the "filling defect" which will have an irregular outline, will be constantly present in every examination, and will not be affected by the administration of medicines.

5. The breast should be thoroughly and carefully examined. Diagnosis is generally easy in advanced cases; "but in the early stages, when radical treatment is so essential, a cancerous tumor may be confused with inflammatory and other benign swellings. In *chronic inflammatory thickening* the skin may be pitted, and the tumor fixed in the breast, and ill-defined; but the whole gland is often uniformly enlarged, scars of old abscesses may be visible, and the glands are swollen at an earlier stage, and to greater size than in cancerous conditions. *Adenomata* are generally clearly limited and freely movable; there is no dimpling of the skin, and the lymphatic glands are not enlarged. *Tense cysts*, when fluctuation cannot be elicited, are similar in most of their symptoms to adenomata; and differ from 'malignant cysts' by the absence of adhesions or extension of the disease to lymphatics. *Sarcomata* are more rapid in growth and soon involve the skin, and do not affect the glands in the early stages. *Duct cancers* are apt to be multiple, are more circumscribed, and are specially distinguished from scirrhus by the bloody discharge from the nipple; they differ also from simple papilliferous cysts of the ducts by the tumor invading the breast. *Epithelioma* of the areola or nipple differs from eczema in its intractability to soothing treatment; and from scirrhus in its superficial and more localized situation, at all events in the early stages. In cases of *doubtful* diagnosis it is advisable to prepare for a radical extirpation of the disease; but first to incise the tumor and remove a piece from the growing edge for immediate examination."—(Buchanan's *Surgery*.)

The patient should be advised, if the tumor is *malignant* (and it is not an inoperable case), that prompt and thorough operation is absolutely necessary. If the tumor is *benign*, the tumor alone should be excised. In *doubtful* cases it is well to imagine the growth malignant until it is proved to be otherwise. If the breast is removed and the tumor is proved benign, the woman has lost a breast; whereas, if it is not removed, and the tumor should prove to be malignant, she will lose her life. The best plan is (with the consent of the patient) to prepare for a radical operation, excise a piece of the tumor, have it examined microscopically, and if it proves to be benign, remove the tumor; if it is malignant, remove the whole breast and neighboring lymphatic glands.

"The presence of a tumor, dimpling of the skin, retraction of the nipple, with cachexia, enlarged lymphatic glands in axilla or above or below the clavicle,

and microscopical examination of an excised piece of the tumor all aid in the diagnosis of malignant growth of the breast. *Treatment* should be early and thorough. However small the tumor may be, the entire breast and its corresponding lymphatic area, as high as the apex of the axilla, should be removed; for, once infection of the lymphatic spaces has occurred, the whole lymphatic area must be looked upon as infected. Successful operations depend upon a knowledge of the *lymphatics* and *extent* of the breast. The lymphatics begin in plexuses around the acini, which converge to vessels running along with the ducts and end in a sub-areolar plexus. From this three or four main lymphatic trunks run to the axillary glands. In addition, lymphatics run along the suspensory ligaments to the skin all over the prominence of the breast from the interacinar plexuses. Also vessels leave the deep part of the breast to join lymphatic plexuses in the pectoral fascia. The plexuses in the fascia run to the axilla, and also communicate with those in the pectoralis major. Lymphatic vessels pass into the mediastinum, and also communicate with those of the opposite breast and axilla. The extent of the breast is much greater than the prominence would lead one to believe. It extends almost to the clavicle, just to the edge of the sternum, down to the seventh rib, and out to the mid-axillary line. The points, then, in operating are that the whole breast, the skin over the prominence, the pectoralis major muscle (except the clavicular portion), the fat, fascia, lymphatic vessels and glands of the axilla must be removed, and in one piece, for if cut across at any part there is danger of strewing cancer cells on the wound and so infecting it with growth. Removal or division of the pectoralis minor facilitates the cleaning of the axilla.—(*Aids to Surgery*.)

6. *Concussion of the brain* is due to a shaking or jarring of the brain by direct (e.g., a blow on the head) or indirect force (e.g., a fall on the buttocks). In the mildest form no anatomical changes take place, but in the severe variety there are lacerations of the brain tissue and blood vessels. If the bleeding from these lacerations is sufficiently great to exert pressure on the brain, or if edema supervenes, the condition is one of compression rather than concussion.

"The symptoms vary from temporary giddiness or stunning, to collapse and death. In a well marked case there is unconsciousness which is rarely complete, in that the patient may be partly roused by shouting, pricking the soles of the feet, etc. The muscles are relaxed, the skin cold and pale, the temperature subnormal, the respirations slow and shallow, the pulse weak and rapid. The pupils are equal, react to light and are usually dilated. The reflexes are sluggish or, in the severest cases, abolished. The sphincters are relaxed, so that involuntary evacuations from the bowel may occur, but retention of urine is more common than its expulsion, owing to relaxation of the bladder muscle. Transient paralysis may exist. This is the stage of collapse, which may last from minutes to hours; it ends either in death or in the stage of reaction, which may be inaugurated by a convulsion, or more commonly by slight movements of the extremities and vomiting. The symptoms mentioned above gradually disappear, the temperature rises, perhaps to 100° F., or a little above, and there is headache, drowsiness, or irritability, which may last a number of days.

"The prognosis should always be guarded, although in most cases complete and permanent recovery follows. The early dangers are compression from hemorrhage or edema, and inflammation of the brain or meninges. Among the sequelæ may be mentioned cerebral irritability, inveterate headache, vertigo, loss of memory, change in character, insanity, epilepsy, diabetes, neurasthenia, and possibly tumor or abscess. Frequently the patient's memory is defective for the events immediately preceding the accident.

"The treatment during the stage of collapse is the application of external heat and the administration of stimulants as in shock. Alcohol, however, should not be given, because of its exciting effect on the brain, and care should be taken not to overstimulate. When reaction has been obtained, the patient should be kept in bed in a quiet room, an ice bag placed on the head, the bowels opened with a purge, and the catheter used if there is retention of urine. The diet should be fluid,

and sedatives used if necessary. If unconsciousness is prolonged, a suspicion of greater injury than concussion should always be entertained. After severe concussion the patient should avoid mental exertion for a number of weeks or months." (Stewart's *Manual of Surgery*.)

Pathology.—"In fatal cases, one finds on post-mortem examination merely the same conditions as obtain in shock, viz., engorgement of the lungs, viscera, and the right side of the heart, whilst the brain presents some lesion of varying severity, from mere punctiform ecchymoses to actual disintegration and disorganization. The symptoms are supposed to be due either to a paralysis of the vasomotor centres in the medulla, or to a reflex inhibition of the heart through the vagus. More recently Duret has suggested that the blow on the skull causes a temporary localized depression of the bone, and this leads to compression of a cone-shaped area of the brain substance. As a result, the cerebro-spinal fluid is displaced and forced downwards to the base of the skull, where it collects, particularly in the fourth ventricle, and thus the vital centres grouped around this space are compressed."—(Rose and Carless' *Manual of Surgery*.)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION
Alabama*	S. W. Welch, Montgomery	Montgomery July 12
Arizona*	A. Martin, 207 Goodrich Building, Phoenix	Phoenix April 5
Arkansas*	T. J. Stout, Brinkley	Little Rock May 10
California	C. B. Finkham, Sacramento	San Francisco June 27
Colorado	David A. Strickler, Empire Building, Denver	Denver April 6
Connecticut*	R. L. Rowley, Hartford	Hartford June 12
Delaware	H. W. Briggs, Wilmington	Wilmington June 21
Dist. of Col.	E. P. Copeland, Washington	Washington April 12
Florida*	W. M. Rowlett, Tampa	Jacksonville June 13
Georgia	C. T. Nolan, Marietta	June 10
Idaho*	Robert O. Jones, Boise	Boise April 5
Illinois	F. C. Dodds, Springfield	Chicago April 5
Indiana	W. T. Goff, Crawfordsville	Indianapolis April 5
Iowa	G. H. Sumner, Des Moines	Iowa City June 21
Kansas	H. A. Decker, Leavenworth	Topeka May 19
Kentucky	A. T. McCormack, Louisville	Louisville May 19
Louisiana	E. W. Mahler, New Orleans	New Orleans June 21
Maine	F. W. Searle, Portland	Portland June 21
Maryland	J. McP. Scott, Hagerstown	Baltimore June 21
Massachusetts*	W. P. Bowers, 1 Beacon St., Boston	Boston May 8
Michigan	B. D. Harrison, 205 Whitney Building, Detroit	Ann Arbor June 11
Minnesota	T. McDavitt, St. Paul	Minneapolis April 5
Mississippi	J. D. Gillesley, Jackson	Jackson June 11
Missouri	G. H. Jones, Jefferson City	St. Louis April 5
Montana*	S. A. Cooney, Helena	Helena April 5
Nebraska	H. H. Antles, Lincoln	Lincoln June 8
Nevada	S. L. Lee, Carson City	Carson City May 2
N. Hampshire	C. Dunnett, Concord	Concord June 21
N. Jersey	A. MacNister, Trenton	Trenton June 21
New Mexico	R. K. McClanahan, E. Las Vegas	Santa Fe June 21
New York	G. M. Wiley, Univ. of State of New York, Albany	Albany May 23
No. Carolina	K. P. B. Bonner, Moorehead City	Raleigh June 11
No. Dakota	G. M. Williamson, Grand Forks	Grand Forks July 5
Ohio	H. M. Platter, Columbus	Columbus June 11
Oklahoma	J. M. Byrum, Shawnee	Oklahoma City June 11
Oregon	R. E. Watkins, Portland	Portland June 11
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia July 5
Rhode Island	A. E. Richards, Providence	Providence April 7
So. Carolina	E. A. Booser, Columbia	Columbia June 28
So. Dakota	H. R. Kennastoo, Ronesteele	Pierre June 28
Tennessee	A. B. DeLoach, Memphis	Memphis Nashville Knoxville July 5
Texas	T. J. Crowe, Dallas	Dallas July 5
Utah	G. F. Harding, Salt Lake City	Salt Lake City July 12

Wyoming	J. D. Shingle, Cheyenne	Cheyenne June 28

*No reciprocity recognized by these States.

The Paris Epidemic of Bubonic Plague.—The Claude Bernard Hospital played the part of a pest house during the incidence of plague in Paris. The period of infection lasted from August to December, 1920. During this period the hospital received 66 patients, but in 23 the suspicious suppurating adenitis turned out to be of the banal sort. This leaves 43 cases of pestous adenitis.—*La Presse Médicale*.

Therapeutic Hints.

Acute Nasal Sinusitis.—Sir St. Clair Thomson considers this condition very amenable to simple treatment. The indications are to facilitate the discharge and soothe the pain. The patient should remain in bed, with the whole head wrapped in a woollen shawl or something that answers the same purpose. Warmth is applied to the affected forehead or cheek by means of a hot-water bottle or other warming process. The following nasal inhalation is recommended, for four minutes every hour or two hours:

R Menthol gr. xxx
Tincture eucalypti

(vel Spirit. vini rect.) ʒiii

S. To a jug half full of boiling water add a teaspoonful of this; arrange a handkerchief as a cone over the jug, and sniff the steam up the nostrils.

The following may be substituted for this:

R Eucalyptol ʒi
Menthol grs. xxx
Tincture of benzoin ʒii

Nose lotions, during an acute sinusitis, are useless, but as soon as the thoroughfare through both nasal chambers is restored, and they begin to discharge freely, an alkaline nose lotion, such as the following, used as a spray, is soothing:

R Sodii bicarbonatis gr. iii

Sodii bichloridis gr. iii

Acidi carbonici puri gr. i

Sacchari albi gr. v

Aquam ad ʒi

A grain of cocaine may be added to an ounce of this spray.—*The Practitioner*.

Artificial Immunization Against the Tubercle Bacillus.—Barbary recommends the following in the production of artificial immunity, based on observations on animals which possess natural immunity against the tubercle bacillus:

Cinnamate of benzyl 0.05 to 0.10

Cholesterin (pure) 0.20

Camphor 0.25

Olive oil, pure, washed in alcohol,

and sterilized at 120° 5.00

To make one ampoule. An injection is given every other day up to ten injections, and then daily for ten days.—*The Practitioner*.

Ivy Poisoning.—The United States Department of Agriculture (Farmers' Bulletin 1166) gives the following simple formula which may be dabbed on the poisoned parts after thorough cleansing or applied by saturating one or two thicknesses of a light bandage:

Zinc oxide 15 grams

Phenol 2 grams

Lime water to make 250 cu. cm.

This may be used in the early or late stages.

Scarlatina.—H. Goldstein recommends the following alkaline mixture in cases of uncomplicated scarlatina:

R Sod. citratis ʒiii

Syrupi ʒiv

Liq. ammon. acetatis

Liq. potassii citratis āā qs. ad ʒiv

M. Sig.—A teaspoonful in sweetened water every two or three hours.

—*American Journal of Clinical Medicine*.

Miscellany.

NEW BOOKS AND OLD.

By JOHN RUTBRAH, M.D.

BALTIMORE, MD.

II. THE EARLY HISTORY OF SURGERY IN GREAT BRITAIN.

If you want to spend a pleasant evening along historical lines you cannot do better than to get *The Early History of Surgery in Great Britain*, by G. Parker. This is one of the newer publications in which the author tries to trace the revival and early surroundings of the surgical art after the end of the dark ages of Europe. It is written in a very pleasing style and seems to be the result of a considerable amount of research and wide reading, and it gives an interesting list of authorities and books of reference. An American notes with pleasure the numerous references to the work of Garrison.

The book makes several points very clear. First, the surgical knowledge of the early Britons was very slight and there was curiously little left of the accumulated stores of medical knowledge that must have been transported to Briton by the Romans and by others. So little is there, indeed, that Parker begins his story at about the year 1000 and from then brings it down to 1850. I cannot pass over without quoting one paragraph which expresses the same thought to which I gave utterance in another place.

Nor were the methods and aims of ancient writers so absurd as the casual reader may imagine. Their quaint phraseology and the absurd theories they put forward to explain their facts, and indeed our habit of selecting ludicrous passages for quotation, are apt to blind us to their work and meaning, and to the identity of their aims with ours in a given operation, for example. In many instances the very methods we have adopted were discovered by them, and then disused and forgotten. Posterity will equally laugh over our technical language, and the theories brought forward in the scientific papers of to-day, when the style has faded with time.

Among the early English surgeons who received more than passing mention is John of Arderne. He was born in 1307 and after a considerable military experience under the Dukes of Lancaster, he practised twenty years in Newark and later, in 1370, removed to London where he joined the Guild of Military Surgeons. His later years were taken up with medical writing, producing various treatises as to "the care of the eyes," on "venesection," on "sinus and fistula in ano," on "the use of rectal injections," on "plants and their uses." He devised an operation for fistula in ano and warned against operating for cancer of the rectum, mistaking it for simple ulceration. He gave a very good account of the diagnosis of cancer of the rectum.

John of Mirfield, of the same period, is also mentioned at some length. He came down to London and became a member of the staff of St. Bartholomew's Hospital and canon of the Priory which governed it. The results of his experience as a quiet and cloistered practitioner, were embodied in a treatise on medicine and surgery written in 1380, called a *Breviarium Bartolomei*.

Surgery and medicine had become separated. Un-

fortunately so, because the physicians spent their time largely in useless disputation, while the surgeons operated without sufficient preparation and study. We may quote one paragraph of Mirfield dealing with this subject:

Long ago, unless I mistake, physicians used to practise surgery, but nowadays there is a great distinction between surgery and medicine, and this, I fear, arises from pride, because physicians disdain to work with their hands, though, indeed, I myself have a suspicion that it is because they do not know how to perform particular operations, and this unfortunate usage has led the public to believe that a man cannot know both subjects, but the well informed are aware that he cannot be a good physician who neglects every part of surgery, and, on the other hand, a surgeon is good for nothing who is without knowledge of medicine.

Parker traces quickly in every period the organization of surgery on the continent and then proceeds to contrast that with the situation as found in England. The first law regulating the practice of medicine and surgery in England was the Act of 1421. Up to this time the regulation of surgeons was by the Barber-Surgeons companies, and was therefore limited to the towns, but there were ignorant practitioners not only in the country districts but in the cities as well. In the period of history in which practically every worker in every line of human industry had to be a member of a guild, it very often happened that there was no guild for the particular branch represented, and the individual had to join some other association, so that it came to pass that there were curious associations; surgeons and barbers were not infrequently associated with laborers in other crafts. The Barber-Surgeons company of London at times contained more members than any other guild in the city. At the present time there is only one legal Barber-Surgeons company in existence and that is in Newcastle where ten members have the freedom by inheritance and are ruled by two stewards pointing to their former division as surgeons and barbers. This is an instance of what is meant by the freedom of the city, which is nowadays an empty phrase, but which in those days meant that the surgeon or worker in some other line might practise his profession or art, and in some cities there were free days when people from the outskirts could also come in and carry on their avocations. The Barber-Surgeons company of Edinburgh was given a monopoly of practice under the charter of James the Fourth, in 1506. The charter provided no apprentice might be taken until he could read and write; no barber allowed to practise surgery unless knowing the things required of the surgeons who, it was said, should not practise "until each had been diligently examined and tested, especially in anatomy and in the nature and complexion of every member of a man's body." Here we must comment on how curiously things wag in this world. In America today alcohol *i. e.*, whiskey, may be bought only on a physician's prescription. The grant of the Barber-Surgeons Company of Edinburgh gave them a monopoly in the manufacture and sale of alcohol.

Parker, along with practically all of the English writers, pays but little attention to the work of John Mayow, although he mentions him in a single sentence. Thus it is that one of the greatest geniuses that England produced is still a practic-

ally unknown man. Mayow, a hundred years before Lavoisier, carried out and described experiments showing the relation of air to combustion, fermentation, and respiration, covering almost the same ground as the famous Frenchman.

One American surgeon is mentioned, William Shippen, 1736-1788, trained at Edinburgh, and the first professor of surgery and anatomy in the Medical Department at the University of Pennsylvania, and at one time Surgeon General of the United States Army.

Taken all in all, this little work will be found well worth reading and besides what it tells of the English surgeons, makes clear the position of the guilds, the work of the early anatomists, gives a good idea of the prevalence and disappearance of leprosy during the middle ages, and the rise and disappearance of bathing establishments, and a very good account of the early hospital period. Before the Reformation there were large and wonderful hospitals completed all over Europe, some of them magnificent structures. With the Reformation came destruction, and the world was medically, in certain ways, plunged back, so that many of the hospitals became almshouses or establishments of very questionable character. The author is to be congratulated on being able to present so vividly so many varied topics related to his subject.

11 EAST CHASE STREET.

Medical Practitioners of Old Bordeaux.—

Durodié has continued his studies of Bordeaux practitioners from the early years of the XV century to the latter part of the XVIII. The first installment which dealt with the earliest practitioners was abstracted in the MEDICAL RECORD. In the final installment which appears in the *Gazette hebdomadaire des sciences médicales de Bordeaux* for November 28, 1920, xli, 48, there are several matters of interest. Thus Pierre Desault was born in the city in 1675, and in a volume on venereal diseases published in 1733, he announced that these are caused by the passage of "infinitely small worms" from one individual to another; thus crudely anticipating the discovery of the gonococcus and treponema. Another local celebrity, although he graduated at Montpellier and removed eventually to Paris, was Jean Baptiste Sylva, who was at one time physician to Louis XV. At the beginning of the XVIII century an epidemic attacked "every woman in Bordeaux." It was evidently a psychoneurosis and Sylva was summoned to his home town from the metropolis. He pronounced the convulsions, which were evidently hysterical, to be epileptic, and having made this diagnosis and stricken the Bordelais with fright, he made a quick exit to Paris. A Bordeaux journal and public opinion denounced Sylva and his diagnosis, whereupon the epidemic disappeared as if by magic. It was believed that Sylva, knowing the characteristics of the Bordeaux population, had effected a psychic cure. For many years there was antagonism between the teaching faculty of the medical school and the local medical union, perhaps the usual feud between the "ins" and the "outs." Of scores of physicians and surgeons mentioned by Durodié few did anything to distinguish themselves. They seem to have been a cosmopolitan lot and Spanish

and Irish surnames are recognizable among those from different parts of France.

Fifty Years of Cancer Mortality in Basle.—Jessen considers this subject in the *Schweizerische medizinische Wochenschrift* for November 18, 1920, i, 47, the period extending from 1870 to 1919. Many tabulations are given. The general death rate shows almost a steady decrease during this period and has been cut in two. The ratio of cancer deaths to all deaths has trebled during the same period. The percentage of cancer deaths to population shows a much less pronounced increase—about 8 to 13. The population of the city has increased from about 43,000 in 1870 to about 134,000 in 1919. A study of Switzerland as a whole, reputed to be the most cancer infested of all the European States, shows great disparities by cantons. For while about 4,000 die annually of the disease in a population of over 3,750,000, some of the cantons show a cancer death rate four or five fold that of others. Basle is low in the list, having for the city a rate of 9.7 per 10,000 inhabitants while in Appenzel the rate is 21.3 and in Obwalden 18.2. The canton with the lowest incidence is Wallis with 4.8. In regard to localities, cancer of the tongue does not seem to have increased in 50 years, in striking contrast to the testimony of London surgeons who state that it has trebled in thirty years. The same may be said of cancer of the larynx, both forms being far more common in males. Jessen also sees no increase in cancer of the esophagus. Cancer of the stomach shows a notable increase in men but only a slight one in women. It attacks urban much more than rural dwellers. Cancer of the colon, unlike any of the preceding, is more common in women, and here an increase cannot be proven. Cancer of the rectum attacks the two sexes alike and an increase cannot positively be shown. Cancer of the breast appears to show an increase in very old women while cancer of the uterus apparently shows little change. The discrepancies between totals and regional figures are not accounted for by the author, who doubtless believes the increase is largely only apparent and due to better diagnosis, longer life, etc.

Morphinomania in Spain.—Dr. Mally of Barcelona has written a paper on this subject which is found in abstract in the *Revista Medica Cubana* for August, 1920, xxxi, 8. The author states that while addiction is much less common in Spain than in the other large culture countries it is common enough and on the increase. The author before his removal to Barcelona had practised 20 years in France, where he devoted special attention to morphinism and other addictions. Of the two methods of sudden or gradual suppression the author prefers the latter. He has treated 172 morphine addicts since coming to Spain, and of this number there were 108 physicians, 4 druggists, 4 nurses, and 7 medical students—in other words 123 were in professional contact with the drug. There were 13 military and colonial functionaries, 11 intellectuals of all classes, 3 lawyers, 6 landlords, 2 artists, 2 students (nonmedical), 1 priest, 5 miscellaneous professional men, and 6 married women. It may have been only a coincidence that 86 per cent. of all addicts were syphilitics.

THE ADVANTAGE OF MENTAL THERAPY IN ORGANIC NERVOUS DISORDERS.

By L. PIERCE CLARK, M.D.,

NEW YORK.

Introduction.—In this clinical study I shall consider the results of mental therapy in the treatment of functional, constitutional, or organic nervous disease. The material is exclusive of those cases with hysteric and psychoneurotic components, and embraces an effort to extend the usefulness of interpretation and treatment of mental therapy in a domain of general medicine not yet well defined or understood. I have carried on this work for several years, and I believe the data are sufficiently justified by time element as well as general effectiveness to warrant a more or less final report.

In Part I I have discussed the probable nature of some of the spasmodic disorders, such as tics and yep neck, an effort being made to explain these affections on a constitutional basis in which both neural and psychic factors coalesce. The enduring results in a series of case studies are given. Part II is devoted to the end-results of a series of cases of retarded depression (mild types of the manic depressive syndrome). Here the time element of an enduring recovery plays no small rôle. Several years of health have now elapsed in the majority of the cases reported. A short exposition of Hoch's theory of the constitutional basis upon which these psychotic states have originated is also set forth. Part III concerns a short elaboration of the constitutional theory of essential epilepsy and the technique upon which a long series of cases has been treated. Some symptomatic or organic epileptics are detailed to show the good results with which well marked and obvious convulsive states may be handled. Part IV is a brief consideration of the neuralgic disorders treated by mental therapy and the end results of such a plan of treatment. Part V is devoted to the general discussion of the more extended efforts of mental therapy in other organic neuroses and visceral diseases, and the possible application of a psychologic theory for their origin.

I. SPASMODIC TORTICOLLIS.

Several years ago, not satisfied with the limitations in the field of analytic treatment of the psychoneuroses I undertook in both the psychiatric and the neurologic field to study such cases that had done so poorly under physiotherapy. I desired to study those types of cases that presumably had an or-

ganic basis or at least a constitutional anlage. While in the past spasmodic torticollis has been considered to have an organic basis, there is an increasing number who believe the psychic element plays the greater rôle in its pathogeny. Those who still believe in an organic basis for this affection, place its lesion in a faulty mechanism of the spinal or bulbar tissues. I have no doubt the anatomic studies (of Hunt and others) incline those who hold to an organic basis to locate more definitely the disorder as a disturbance in the functioning of the midbrain, caudate nucleus and putamen. Some somatists believe the essential pathogeny of the affection is in still higher regions, even to the cerebral cortex itself. The pathogenic issues are not likely to be settled in the immediate future, inasmuch as hardly any one pretends to isolate such overacting nerve cells even by the most exact technique, even supposing autopsy material be forthcoming. The neurotic heredity so frequently present in the condition gives others who approach the pathogeny from this organic standpoint additional reasons for not more concretely locating the lesion. The claim that it is due to a primary defect in the nerve elements themselves, a sort of imbalance of natural functions of the nerve centers concerned, is still less definite or susceptible of proof; nor is the issue of the exact anatomic pathogeny of the disorder solely of academic value, for if it be proven of definite somatic causation one would hardly expect the disorder to be greatly influenced by other means than a strictly organic therapy.

Up to comparatively recent years, even with the most intense application of physiotherapy, this affection has failed of even temporary relief, thus lending additional evidence of its organic origin as well as the general hopelessness of its permanent relief. A few workers in this field who have excluded the different forms of so-called hysteric spasm and have then applied mental treatment to the essential type of the disorder, have usually experienced relapses after a more or less apparently complete recovery, so that one might conclude that when a torticollis has become at all definitely developed, the lesion, whatever it may be, was not only organic in origin but was hopeless of permanent cure.

With such despairing issues confronting us, I began the psychogenic study and treatment of a series of the disorder in its pure type. I fully realized that nothing but the so-called essential cases of this affection would be worth while. Not only should the ordinary hysteric cases be completely eliminated, but instances of the disorder of short duration such as those of a few weeks' stand-

ing needed to be excluded. With this idea in mind I selected the most inveterate cases. In all, my experience was limited to some half dozen cases now under observation from three to eight years. Before making a short digest of this work and my results, I may state in all fairness that while psychoanalytic methods were those predominantly used, all other forms of suggestive and supportive therapy also were employed. However, in no instance were drugs or physiotherapy such as massage, electricity, etc., used. There is no doubt in mind, moreover, that the disease, aside from that of a hysteric character, is really as organic at bottom as all other similar spasmodic diseases, but probably this basis is not in the sense which that term is ordinarily employed. The imbalance in the centric functioning of the several nerve centers controlling the disorder may be the real fault, plus something else added (to be stated later). While this in itself is not an exact explanation, it is the best that I can venture. The same or similar interpretation may also hold true for the essential pathology of many epilepsies and spasmodic syndromes.*

CASE I is that of a middle-aged man, unmarried, now nearly eight years entirely free from a severe type of spasmodic torticollis. He had a full nerve resection of the right spinal accessory and the external roots of the third and fourth cervical nerves. This as well as all other plans of physiotherapy proving of no avail, analysis was undertaken for the greater part of two years. The gradual additional involvement of the splenius and trapezius muscles modified the ordinary picture of torticollis. A history of motor instability in tremors, unrest, and "fidgety" makeup was revealed. The improper subordination of these inherent defects of the motor mechanisms were fairly well handled until the stress of a maladjusted business and social life removed the controlling psychic factors and the patient became a confirmed ticur. He had had his disorder for about three years before the analytic treatment was undertaken. After his recovery he reentered his old employment and made good, having been advanced in position and salary. He has enlarged his avenues of good fellowship through club associations. The innate feelings of inadequacy have been fairly well eliminated both by the analysis as well as the actual benefits derived from his more advantageous position. Material proof of the increased esteem of one's fellows is, perhaps, one of the best medicines for feelings of inferiority. His former fits of temper, depression, and general restiveness at home were so improved that a disinterested member of his family largely confined her praise of the treatment to the marked permanent changes in his personality.

CASE II is that of a middle-aged woman, single, who had a right spasmodic torticollis with a retrocollis combined, existent for about six months before analytic treatment was instituted. The patient had an attack of chorea, which persisted for months following acute rheumatism. After a free period of several years the chorea reappeared at twelve and endured for a short time (two months). She had a defective motor heredity and was a restive, shy, timid child. A one-sided love affair seemed to have been the psychic cause of disturbing the motor balance and control and the tic movement developed during the breakdown that followed. The neurotic element was here most marked and the erotic fancy was quite distended. In consequence it

*For further details on the subject, as well as case reports, see: "Some Observations Upon the Etiology of Mental Torticollis," MEDICAL RECORD, February 7, 1914; "A Further Study Upon Mental Torticollis as a Psycho-neurosis," MEDICAL RECORD, February 28, 1914; "Remarks Upon Mental Infantilism in the Tic Neurosis," MEDICAL RECORD, March 28, 1914; "Further Observations on the Tic Neurosis," MEDICAL RECORD, January 30, 1915; "The Results of the Psychic Treatment of Mental Torticollis," MEDICAL RECORD, July 14, 1917.

was thought that an analysis would not be quite so much of a test for an organic condition as in Case I, but the results proved that whether one stressed the psychic factors or not the end results were less satisfactory than in Case I. After the first month's treatment the patient lost the pain, tenderness, and tension in the spasmodic muscles, and the tonic spasm changed to a clonic one over long periods (15 to 30 minutes). After three months' treatment she made slow progress, and at the end of six months but little further improvement was shown. The main reasons for the relief stopping here seems to have been that she found it impossible to sublimate further from the love experiences that brought out the disorder. At present she is keeping house for a relative and engages in religious and charitable work at odd moments. She has not the innate ability or opportunity to develop a proper emotional outlook and economic independence, as in Case I, hence the psychic perturbations must still permit many lower automatic motor activities.

CASE III is that of a young man who had had his torticollis for several months when I first saw him. There was retro as well as torticollis and some involvement of all the muscles of the shoulder girdle. He has been entirely well now for nearly four years. He had motor instabilities as a boy, was clumsy and incapable of doing things with his hands. His final breakdown came after disappointments in business and a love affair. In the course of three or four months he sufficiently recovered to warrant his going away with another torticollitic patient (Case IV) for a camping trip. The experiment of several months' association, while good for both, went poorly so far as companionship was concerned, and they ended by mutually accusing each other; but both showed marked improvement. The line of betterment in this case was shown in his decided change from a state of extreme invalidism, in which he did nothing but bemoan his fate, to becoming industrious; he took up wood-carving, shovelled snow, sawed wood, and took long walks without attendance. I have rarely seen a torticollitic so invalidated by his disorder as was this patient at the beginning of his treatment. It took two men to help him about aside from his own constant efforts to keep his head from "twisting off." After a year of treatment he finally went back to work in the same shop and fully adjusted himself to the old job. He perfected his attitude toward his superiors so that he has been advanced in position with increased salary. He finally made a good adult marriage and has a comfortable and happy home. Outside of business hours he engaged in war work. He became a good mixer among his fellow workmen and community associates. From a vacillating, indecisive character he has now gained an independent position, both socially and economically.

CASE IV is that of a man of 32 years who had a right spasmodic torticollis of two months' duration when he applied for treatment. He had tried all sorts of drug and physical therapy without effect. He had a mildly severe grade of neurotic constitution, was tender-minded and sensitive and had trouble with his superiors. A feeling of inferiority and much tension was engendered and he finally had a nervous breakdown and a torticollis. In the ultimate analysis, as in all the other torticollitics, the underlying inferiority was brought to the fore. Three months' analysis almost completely restored this patient to the normal. This speedy recovery was due partly to the fact that his torticollis had been very recent when he came under treatment (three months); also, when the underlying defects of inferiority, infantile attachments and fixations were once psychoanalytically released, there was a more spontaneous readjustment of his attitude toward adult life. Soon after recovery he was married. During the past three years he has kept continuously at work and has been able to successfully make an independent career for himself.

It may be the same principle holds true here as in the advice given by the old judge to his young colleague: "Give your decisions, but reserve your reasons for them." One is constantly importuned to lay down some sort of rational explanation of the nature of the affection itself as well as the

manner by which cure is brought about. It is unnecessary to say that both attempts are not only tentative, but may not be worth the risking. However, the following may be hazarded: If we assume that spasmodic torticollis and tics are really disturbances in the functioning of certain nervous elements in the basal ganglia, how may we explain the radical cure by purely mental therapy? At the outset we must select the constitutional imbalance or instability theory as the more rational hypothesis rather than a nerve lesion as ordinarily understood. In many torticollitics these motor defects can be presaged, in fits of trembling, tendency to cramp, spasm disequilibrium, or lack of smoothness in muscular movements in early childhood. Although these different motor instabilities are subtended by widely different nervous structures, they are as a whole evidences of an imperfect development of the motor mechanism. If we go further and assume a corresponding instability of the highest cortical elements also, and even a defective psychic balance—although in this latter statement we assume the impossible chasm of a psychophysical parallelism, yet the combination of such a chain of defects makes possible the advent of the disorder, especially when some emotional stress or shock precipitates the disintegration of motor control of lower and perhaps less stable centers. According to the teachings of Hughlings Jackson, the highest moral inhibitions, those of the psyche, let loose an unbridled anarchy in previously disorderly lower nervous centers and tics and spasmodic disorders may result. By this hypothesis it is more understandable that by reestablishing the proper superior psychic control we may recover the torticollitic from his disorder. It is also easier to understand that where the main psychic traits of mental balance and control are not sufficiently strong, or even when the fault is analyzed, the individual cannot bring about an orderly mastery of the lower nerve centers especially when the automatic controlling mechanism in the basal ganglia is weak. In former reports I felt it necessary to maintain the strict psychogeny of spasmodic torticollis and tics, but more recent studies show me that the above interpretation is, perhaps, the more reasonable one. One may thus maintain that these affections may still be regarded as organic, but of that nature of constitutional instability of the lower nerve centers wherein a disturbance and loss of control of a superior inhibition mechanism, the psyche, really permit an exhibition of the inherent motor defect as we know it clinically. No doubt a similar plan of treatment would also be applicable to many other so-called functional tremors and spasms provided it were undertaken early enough and the fundamental disorder of motility were not any more deeply conditioned upon a progressive deteriorating lesion or a part of a much wider syndrome. The main advantages of this plan of therapy are not only its apparent completeness of cure and its enduring character, but also the individual so recovered has gained a wider usefulness, personally, socially and economically. Many an obtruding and disabling character fault, such as are commonly removed by analysis, were swept out of existence in the process of the specific therapy. At least three of my patients were able to assume

the duties of married life and improve their economic standing in the community without exhibiting any tendency toward relapse.

II. PERIODIC OR RETARDED DEPRESSIONS.

While one may not say that the manic depressive syndrome is the manifestation of an organic lesion of the brain, numerous theories to this effect are in evidence. It has been held that the loss of weight, vasomotor changes, amnesia and gastrointestinal disorders that appear in the early stages of this syndrome are strong indications that the disorder has an antecedent physical or chronic basis. Hoch¹ has outlined the constitutional makeup of this mental syndrome in which he stresses the metabolic changes as being the predominant characteristic. One can hardly count such bodily changes as other than precipitants of the mental syndrome inasmuch as many of these are accompanied by such biologic epochs as pregnancies, childbirth and lactation which are as much psychic as somatic events of genetic moment. An interesting theory of the manic depressive syndrome is that of Ward,² in which he likens the illness to that of Raynaud's disease; here the disorder is a vasomotor disturbance of the frontal lobes and by an hypothesis of congestion or anemia of these parts of the brain induce overexcitation or depressions of the lower centers in the cerebrum and basal ganglia, thus accounting for the different phases of the syndrome in its physical and psychic characteristics. Unfortunately the hypothesis rests upon our slender anatomic and physiologic knowledge of the frontal lobes and still more unproven psychopathology of the mind as a psychologic entity independent of neurologic foundation. Finally one may say that there is no essential clinical substantiation that the vasomotor system is extra labile in this mental syndrome than in countless other psychoses the pathology of which rests upon quite other circumstances of derangements of circulation. There can be no doubt, however, that this psychosis has a very strong hereditary basis and in that sense may be considered a constitutional affection, in the same way as neurologic states, the spasmodic affections, epilepsy, and even dementia præcox. Undoubtedly brain lesions found in this psychosis when present must be considered in the light of a "pathologic symptomatology" of the disease; that is, the lesions are in the nature of results, or effects, rather than a cause. Of course it is well known that the episodic manifestations are commonly enough recovered from, but the real problem in this field of therapeutics is to discover a plan of treatment which shall so influence the fundamental makeup or constitutional inheritance that the episodic recurrences may be obviated. As is well known, the individual attacks cure themselves whatever the plan of treatment, but an enduring arrest in the cyclic episodes by different systems of therapy has failed in any large material. With this latter view largely in mind, I undertook, several years ago, a thorough analysis of a few selected cases. In all, about a dozen cases were requisitioned and carefully followed both in treatment and in after observation. A brief statement of the end results may be of therapeutic interest as some, and indeed most of the cases, have now been free for

several years from subsequent mental episodes. From the general nature of the cases relapses might have been expected. We may avoid undue criticism if we speak of these cases as states of arrest rather than cures.

In order to connote a working hypothesis in the study it was necessary to assume some more or less definite psychic rationality for the disorder. This is at hand in that which has been put forward by A. Hoch and which in turn was drawn from the teachings of Freud. In brief, this hypothesis is as follows:

For some time antedating Freud's work it was known that in so-called posthypnotic suggestion it was possible to experimentally create motives for action, and that they could be carried out without the motive itself entering into consciousness. It remained for Freud, however, to reveal to us a new world of such unconscious motives of which he had previously been comparatively unaware. He insisted that these motives of earliest life did not disappear from the individual's life, but underwent a further development, and from the very nature of their further development the original form of their existence ceased to be a reality to the normal adult consciousness. Freud found, on analysis, one of the greatest unconscious motives was a tendency for a strong attachment of the child to the parent, and particularly a great love for the parent of the opposite sex (Oedipus complex). One recognizes at once the possible rôle such a love attachment might play in the development of the love-instinct. But adult love contains sensual elements which are not present in the child, and can, therefore, play no part in that tender feeling toward the parent. As puberty approaches, however, these sensual elements appear. It has been shown that the great task of puberty is to dissolve the bonds of the home tie and to transfer a part of the affection shown previously for the parent to new objects, in the service of the instinct of propagation. This puberty-process is not possible to every individual, and the assumption is made that in such instances the trend of the sensual impulse then flows in the direction of the tender feeling formerly felt for the parent. But the conscious personality strongly opposes this process, hence this sexually intensified part of the attachment for the parent remains repressed and unconscious. One may say, therefore, that in the course of adult development certain normal steps remain undeveloped, or are arrested. Hence this defect of undeveloped instinctive desires—which later are the very core of the personality—results in a defective adaptation, in the sexual sphere especially, and, as has been carefully pointed out, when one states there is a sexual cause in every neurosis it does not necessarily imply a sexual cause in the adult sense, but in the sense that the cause lies in the imperfect development of the instinct. It has been shown that the unconscious has different depths, and that the infantile motives just mentioned are undoubtedly among the deepest repressed strivings. But in order to understand these infantile motives aright one needs to free himself from the ordinary adult logical way of thinking and meet the situation on the infantile level. Knowing that Freud has spoken of sexual causes and the child's longing for the parent, many laymen and also physicians

translated this statement into terms of adult sexuality. This is probably wrong, for adult sexuality has many qualities added at puberty which have no such formulation in the infantile life. Often the ideas of desire, expressed in the depressive psychosis in particular, are much more vague and not infrequently express a mere wish for possession. This is well shown in the so-called benign psychoses wherein the longing is often expressed as a wish to die with the father, or for the removal of the mother. For instance, a woman may become neurotic when she becomes engaged. After marriage she refuses to submit to the marriage relations and then develops a psychosis in which the ideas expressed are essentially that her marriage is annulled, her mother is dead, and that she herself is following her father into his grave and is united with him. In other words, it may be inferred in such a case that the woman was unable to adapt herself to her married life and therefore regressed to a union with the father. It can readily be seen that this psychotic setting is not sexual in the adult sense, though it is an evidence of imperfect adaptation of the sexual life. There still remains another important point, namely, the thoroughly illogical nature of the above example. On logical grounds it is absurd to wish—and we regard the delusions as expressions of unconscious wishes—that the mother should die, when all that is desired is to be united with the father in death. But the psychosis does not think logically, but autistically, as Bleuler has expressed it. The wish for the mother's death or removal exists, because to the child she is the rival in the affections of the father. We must not forget that the ideas expressed in psychoses are often, so far as we know, direct emanations of unconscious desires which cannot be understood by the observer or the patient when standards of logical thinking are applied to them. And, when we try to cast them into logical or adult form, we are doing something which is, strictly speaking, not possible, and the formulation is apt to become one-sided and artificial. To recognize this is important. The vagueness of these trends is not due to our imperfect knowledge of them so much as to their very nature, and we are not improving matters if we attempt to make them clearer than they really are.

CASE I* was that of a married woman who had passed the climacteric. She had attacks of simple retardation alternating with most marked depressed states for twenty-five years. The alternations were semi-annual. The depressions did not go so deep as to materially disturb the organic life nor did she more than vaguely contemplate suicide. She had no children. The precipitating cause was little in evidence, but there was a marked heredity to the disorder in temperamental makeup. After a fairly exhaustive treatment, lasting four or five months, she succeeded in reestablishing her home and social interests, and has almost uninterruptedly enjoyed good health since, now a period of ten years.

CASE II was that of a middle-aged widow with one grandson. She had just passed the climacteric. She had several slight depressive episodes and one very severe attended by organic reactions of suicide, refusal to eat, lost visceral sensibility, etc. She has been en-

*For detailed histories see "Mechanism of Periodic Mental Depressions as Shown in Two Cases and the Therapeutic Advantages of Such Studies," *Review of Neurol. and Psych.*, October, 1914; "Some Therapeutic Considerations of Periodic Mental Depressions," *MEDICAL RECORD*, February 9, 1918.

tirely well for six years. Her attacks at the time of treatment were occurring every five or six months. She fully regained her previous social and economic capacity.

CASE III was that of an unmarried man in the middle thirties who had attacks of simple mental retardation for thirteen years, the longest free period during that time being less than two years. Treatment has resulted in the patient's avoidance of any future attacks of depression now over seven years. There has been a steady improvement in his social and business conduct and elimination of previous alcoholic excesses.

CASE IV was that of a married woman who had passed the climacteric and who had her first attack of simple retardation at twenty years of age, accompanied by thoughts of suicide. She has had more or less severe attacks every few years until five years ago, when the state of depression was more or less persistent, with fluctuations of intensity in the depressive symptoms from time to time. Analytic treatment was carried on for a year, and its fruitful results are shown in her adaptation to home and community life, absence of vestigial symptoms of "blue spells," greater productive work, absence of irritability and fatigue, and less sensitiveness and inactivity. She takes a continuous interest in her household affairs and has been free from depressions for four years.

CASE V was that of a woman now in the late twenties who has had several classic manic and depressive episodes since her seventeenth year. The analysis was undertaken at the beginning of the sixth depression, following a manic excitement and continued for six months. The results were shown in the patient's complete readjustment to her mother, brothers, husband, and child. Three years ago the husband and mother reported that "for the first time in ten years she has been perfectly normal without nervous and physical symptoms." She has resumed her social and household duties with content and is quite serene and happy.

CASE VI was that of an unmarried woman in middle life who had for five years a circular type of mild depression and excitement, each lasting six months, the condition developing gradually out of the "natural" fluctuation of her mood for ten years before definite depressions and excitements occurred. During the latter part of this five year period of mental disorder, while in a hypomanic state, a type of paranoid ideas developed and she undertook analytic treatment during the depression which followed this period. The treatment was continued for several months. The depression promptly ceased after the first month's treatment; in the ordinary course of previous attacks such change was not due for at least two months later. The patient was able to continue at her rather complicated intellectual and literary work and at the time when the hypomanic period might have been expected it failed to appear. After three years' freedom from vestigial symptoms she returned for a short analysis of a mild depression, hoping to curtail it before deeper symptoms occurred; unfortunately her present state is sufficiently comfortable to make her unwilling to attempt further analysis. One may at least say here that this patient has undergone great mental reconstruction, but she is probably the least satisfactory as a clinical showing of all the cases of my series.

In applying analysis to these individuals, several difficulties are encountered. First of all is the strong hereditary inheritance which gives a more or less distinctive constitutional makeup. As might be expected, these strong trait tendencies make intense the infantile fixations or defect of primary instincts for adult adaptations. Even when these hereditary evidences are not strongly in evidence, the very earliest distortions of the instinctive life make it doubly difficult to bring these primary faults to mind so that the individual may get an experiential knowledge of them. For upon the degree of lasting insight must the final good results largely depend. The transference in such individuals is fairly easy, for the patient to the analyst, and vice versa. The permanency and con-

stancy of an enduring transference is, however, difficult. From the very nature of the makeup of the depressant one might easily expect this, hence they should be taken in hand at the very earliest age, as better results are forthcoming before they have become sophisticated or disillusioned, and moreover at a time when life itself holds its greatest reward. In the deepest condition of depression the state itself discourages analysis by the association method, and the patient bears up poorly under a strict manner of approach. Even though the dreams are fraught with death and despair, symbols which are common enough in such persons, one must persevere and adjust the analysis but not discontinue it. One may work upon less deep levels, in the conscious or foreconscious, having the patient keep in mind that such analysis is by no means final or conclusive. The best periods for analysis are when the patient is just entering, or just emerging from, a depressed state. Should the transference become too intense through faulty technique or otherwise, the work on the main problems should cease and analysis of the transference itself should succeed for a time. Of course the general bien-être of even the slightest grades of elation disestablishes the transference and no real analysis can be pursued. I have never been able to proceed with the analysis in a negative transference which is so frequently encountered; the state of tediousness and boredom seems to forbid of a sufficiently constant negative transference. While it may sound unsympathetic and also the facts may have been drawn from too few data, yet intense preoccupation with the manic depressive group as a whole gives the impression that such individuals do not take a deep-rooted grasp upon the foundations of life, and though usually pleasing in personality have not great staying qualities. Just as the epileptic has many of these stabilizing qualities even to excess, the depressant is more superficial and possesses too little tough fiber for life's stress and storm. It is interesting and at the same time discomfiting to the analyst to review what the members of this group indicate afterward what really helped them most as the result of treatment. They all state it was the transference, and none are able to give any accurate or precise statement of the main faults disclosed in the analysis. While this explanation may not be uncommon in even the simpler neuroses I find the depressant's attempts at explanations are cruder than the average analytic cases. Whether the analysis is really so painful as to require being repressed or whether the piecing together of the personality faults is too difficult, one may not say. Perhaps the hypothesis is of sole value to the analyst who, through his insight and mastery of the problem makes the patient's proper transference possible.

It is important to note that a whole series of accessory psychotic attitudes in the depressives were also remedied as in the torticollities. Those here specifically referred to are alcoholic excesses, jealousies and character failures including paranoid trends. The latter were so pronounced in two cases as to cause a diagnosis of true paranoia to be made, but the unsystematization of the trends of ideas and the general lack of a retrospective falsification of memory as well as the absence of the

paranoid character previous to the onset of the psychosis, made one doubt the true nature of the syndrome. The fact that the state was entirely removed in both cases though persistent long after the antecedent depression was positive proof of the benign character of the paranoid trend in both.

(To be continued)

ON GALLSTONES.*

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE NEW YORK POSTGRADUATE
MEDICAL SCHOOL.

GALLSTONES are so common that it is well worth while to make them the topic of this evening's talk. They are frequently found at autopsies, some pathologists maintaining that they occur in about 10 per cent. of the cases. Not all persons affected with gallstones appear to manifest distinct symptoms during life. Some clinicians maintain that only about 5 per cent. of the gallstone carriers are troubled with mild or severe lesions due to the calculi. Kehr, one of the most eminent gall-bladder surgeons, asserts that but 1 per cent. of the gallstone carriers ultimately require surgical aid for relief. This view, however, is not shared by all, and some surgeons go so far as to say that all gallstones are pathological and are accompanied by symptoms, though these frequently fail to be recognized.

Gallstones are much more commonly found in women than in men, the relation being about two to one.

With regard to the etiology, Naunyn's theory of the infectious origin in the formation of stones is generally accepted. According to this clinician, the calculus is always preceded by an inflammatory process of the gall-bladder. Infectious diseases of a general nature frequently play a part and lay the foundation which later on leads to the development of a calculus. Thus typhoid fever, pneumonia, and influenza are often the instigators of a cholecystitis. Typhoid bacilli, various streptococci, and the *Bacterium coli* have been found in the gall-bladder and are believed to have originated the disease process there. Aschoff and Baccmeister, however, maintain that gallstones, especially the cholesterol variety, can form without the aid of bacteria through conditions favoring the stagnation of bile in the gall-bladder.

Gallstones are found either in the gall-bladder proper or in the various biliary ducts—cystic, choledochus, the common duct, and also in the hepatic duct. They are formed principally in the gall-bladder and, though rarely, in the biliary canals of the liver.

The symptoms will vary according to the place of location of the stones. The following possibilities can be discerned:

1. They are found permanently located in the biliary ducts or in the gall-bladder.
2. They may be movable, passing from the biliary canals or the gall-bladder through the choledochus into the duodenum.
3. They can become encapsulated, in which stage

they may cause inflammation, pus formation, or ulceration of neighboring organs.

4. Gallstones may be found in the intestinal tract, and may either be passed easily or become incarcerated and then cause severe symptoms, principally those of obstruction.

Stones in the gall-bladder proper cause either no symptoms or very vague and indefinite ones, such as a feeling of pressure in the region of the liver or reflex gastric symptoms. When, however, they have attained a certain size or are distending the gall-bladder in a pronounced manner, more definite symptoms appear, such as pains, chills, etc. When the stones wander and reach the cystic duct, they are apt to occlude this canal and cause severe colic.

The severity of the attack will depend upon the size and shape of the stone and the accompanying infections, because the walls of the mucosa of the duct are injured and exposed to different micro-organisms. Such a stone that has begun to wander may either successfully reach the choledochus and thence be expelled into the duodenum, provided its size permits, or it may be forced backward into the gall-bladder and then the attack will subside. The first alternative—the passage of the stone into the intestine and its subsequent exit through the rectum—is designated as a successful attack; while the retrogression of the stone into the bladder is termed an unsuccessful attack.

In some instances the stone may move up to the neck of the gall-bladder and close the cystic duct and become anchored there, so that no bile can enter the gall-bladder. This frequently leads to an enlargement of the gall-bladder, due, not so much to its bile content as to retention of its own secretion, mucus, etc., which accumulates there without the possibility of being emptied. This may proceed to such an extent as to lead to ulceration and ultimately to perforation of the gall-bladder.

Encapsulated stones, likewise, may remain quiet without leading to serious lesions, or they may at times cause various pathological conditions, i.e. pus formation, ulceration, and rupture or perforation into a neighboring organ. Thus a communication between the gall-bladder and the duodenum is not rarely found.

When the stones have entered the duodenum, as a rule they pass out without any further manifestation. In rarer instances, the stone which has reached the duodenum by a perforative process is too large to move further and it becomes lodged at some place in the intestinal tract; spasm of the muscularis of the intestine and irritation of the mucous membrane lead to incarceration of the stone and symptoms of obstruction. Under such conditions the disease may assume a critical aspect and terminate fatally in a few days, unless the ileus is relieved. Frequently, however, this type of obstruction undergoes a favorable change, the spasms letting up and the stone moving further on. Occasionally there are periods of grave conditions followed by remissions, the reason for these being that the stone in conjunction with the spasm causing obstruction becomes released from time to time, in such a manner that the fecal contents may pass by it, although with difficulty. In such cases ultimate recovery may take place through the successful

*An address delivered before the Lackawanna Medical Society on Tuesday, Feb. 1, 1921, at Scranton, Pa.

passage of the stone. If not, they offer a favorable prognosis when operated upon.

Patients afflicted with gallstones may present typical symptoms, as already mentioned, or the symptoms may assume an atypical course and simulate the most varied conditions.

Diagnosis.—A minute history of the progress of the disease will help greatly in making a correct diagnosis. If there have been typical attacks of severe colicky pains in the upper abdomen, especially toward the right, radiating upward toward the shoulder blade; lasting a short period of time—from half an hour to six hours or even a day or two, followed by an interval of well-being over a considerable period of time—say from a month to a year or so, the diagnosis of gallstone is quite probable.

Jaundice following the attack initiated by pain is another evidence of stone. Although these signs are quite conclusive, there are exceptions in which similar conditions may be caused by altogether different diseases. It is therefore of the greatest importance to have additional signs to aid us in clearing up the diagnosis. It is self-evident that these objective signs of which we are now going to speak are of even greater importance when the symptoms and history of the case are not so very typical of gallstones.

The physical examination frequently shows enlargement of the liver; occasionally the gall-bladder, as such, can be palpated and felt underneath the liver; it has then the form and character of a small pear-shaped elastic bag. This, of course, can occur only if the gall-bladder is filled with stones or fluid and so enlarged as to protrude from the liver. Very often the palpation of this organ elicits pain.

Within recent years the x-ray examination has enabled the physician to discover gallstones by the shadows cast in a considerable proportion of the cases. It is now assumed that from 15 to 25 per cent., or even more, of the gallstones can be recognized in this way.

The examination of the bile by means of the duodenal tube in the fasting condition of the patient is of great value. When stones are present in the gall-bladder or in the ducts, the bile is almost always turbid; usually, the more pronounced the degree of the turbidity, the more the color deviates from the normal golden yellow, the greater is the pathological condition associated with the stone.

Microscopically, the bile specimen obtained from a patient with stone shows cholesterol crystals of different shapes, either a few very large ones or tiny ones in great number. Bilirubin crystals are likewise found; occasionally, pus corpuscles and various bacteria are also encountered.

Lyon of Philadelphia has suggested the injection of magnesium sulphate into the duodenum before examining the bile. He thinks that by this method he can segregate those parts of the bile coming from the common duct, the gall-bladder, and also from the hepatic duct. In testing his procedure, however, I have come to the conclusion that the best results with regard to diagnosis are obtained from the fasting specimen, and that at present the segregation of the bile is not possible.

As an instance of the importance of the bile examination, I will mention just one case in which

a wrong diagnosis was made in a first-class hospital in this city. Briefly, the case is as follows:

A female patient, about forty years of age, was complaining for about six months of gastric distress and vomiting, accompanied by a loss of flesh of about forty pounds. After a thorough examination in the hospital, the diagnosis of cancer of the stomach and pylorus was made, and operation was advised for that malady. The patient then consulted me. I found her stomach quite dilated. Examination of the gastric contents showed no gastric juice, the contents after a test meal being almost neutral; the stomach in the fasting condition was empty. The string test showed that the pylorus was permeable, and that no ulcer was present, the end being tinged golden yellow and no blood stain above. The duodenal contents obtained in the fasting condition showed a dirty-looking bile, resembling pea soup, and containing bilirubin calcium crystals and numerous pus corpuscles. Pancreatic ferments were present. Based principally on the findings of the direct examination of the bile, I made a diagnosis of gallstones and advised operation for their removal. Dr. Willy Meyer operated upon the patient in the Post-Graduate Hospital and found a gall-bladder filled with tiny stones—two to three hundred or more. The patient made a rapid recovery and has since regained her forty pounds, and is alive and well now, some four or five years later.

Treatment.—The treatment is both medical and surgical. The medical treatment has for its purpose the relief of the suffering and, if possible, the elimination of the offending agent. In some instances, when the stone is small, this is feasible. Drinking of large amounts of water, leading a hygienic life, frequent eating, and drinking of some saline aperient water are all favorable for this purpose. In biliary colic of a severe character, the pain is best subdued by a hypodermic of morphine in conjunction with atropine. During and following the attack, rest in bed is essential.

If the attacks are frequent and perhaps accompanied by fever and a high leucocytosis with an increase of polynuclears, operation for the removal of the stones should be considered. Jaundice, which has developed after a biliary colic and has not subsided after a period of three to five weeks—showing that the common duct is occluded—is another indication for operative intervention. Operation is also indicated when an empyema of the gall-bladder is manifested by chills, high leucocytosis, and pain, and a perforation is suspected—sudden cramps, rigidity of the abdominal walls, etc. In the latter case, the sooner the operation is done the better.

While I am not of the opinion that all gallstones require operation, I would recommend that, in case the abdominal cavity is opened on account of some other condition, if gallstones are known to exist or are discovered at the operation they should be removed as a prophylactic measure, even if the patient has not presented symptoms from them.

Contraindications to Operation.—Severe heart or kidney troubles, old age, and jaundice of very long standing, are in themselves contraindications to operation, on account of the great danger to which the patients are exposed under such circumstances. The gravity of the disease will help to decide whether or not operation should be undertaken.

Dementia Precox Cured by Pluriglandular Opothérapie?—Marie and Fourcade claim that not only marked improvement but actual cure may follow the prolonged use of combined thyroid and testicular extract.—*Le Presse Médicale*.

TWO CLASSIFICATIONS OF BRIGHT'S DISEASE.

By ROLFE FLOYD, M.D.,
NEW YORK.

It is the object of this paper to compare briefly Delafield's classification of kidney diseases with that of Volhard and Fahr. Delafield, working first at Bellevue Hospital and later at Roosevelt in New York, at a time when autopsies could be performed on nearly every fatal case, published his classification in a series of papers about 1882, later compiled to form two volumes entitled "Studies in Pathological Anatomy." In later articles on the subject his original scheme was a little amplified but never radically changed, and his last publication, "Lectures on the Practice of Medicine with Cases and Charts," 1903, gives his final views, still essentially in agreement with those of 1882.

Volhard and Fahr, working at Mannheim in collaboration, the former on the clinical, the latter on the pathological side, published their classification in a volume entitled "Die Brightsche Nierenkrankheit" in 1914, again on the basis of autopsies on almost every fatal case.

About a generation separates these two pieces of work, each focuses the previous work done on the subject by others and each constitutes a notable achievement in itself, so their comparison is of interest.

First Delafield's views, then Volhard and Fahr's are given, each as nearly as possible in their own language. Then a comparison is drawn between the two conceptions.

I. DELAFIELD'S CLASSIFICATION.—Delafield in his original article writes as follows:

Acute Bright's Disease.—There is a general agreement, at the present time, that there is certainly one morbid condition to which the name of inflammation can properly be applied. This condition is characterized by an accumulation of blood in the vessels and an escape of the plasma, white cells and red cells from the vessels into the surrounding tissues. The inflammation is, therefore, called an exudative inflammation.

It may be that the congestion and escape of the elements of the blood from the vessels will be the only morbid change; or there may be added degeneration or death of the surrounding tissues, or a growth of new tissue. It is evident, in such an inflammation, that it is the blood vessels which are principally concerned. How and why it is that their walls are so changed that they allow the elements of the blood to pass through them we do not know, but the ordinary production of serum, fibrin, and pus in this way is a matter of everyday observation.

The introduction of certain poisons into the body is regularly followed by changes in the cells of the viscera. The poisons which exert this effect are ordinarily mineral poisons, such as arsenic, mercury, and phosphorus; or the poisons of infectious diseases, such as diphtheria, typhoid fever, etc. According to the quantity and virulence of the poison received into the body, there are more or less marked changes produced in the cells of the viscera.

Small doses of such poisons, acting only for a moderate length of time, produce a simple swelling of these cells. The cells are swollen, more opaque, more coarsely granular. They are not dead, nor broken down, nor do they contain any new substances; the change in their appearance is due to the swelling of the network which forms a part of every cell. Under these circumstances there are either no changes at all in the blood vessels of the viscera, or a slight congestion, with, perhaps, a little exudation of serum.

Larger doses of such poisons, or more virulent

poisons, or a longer duration of the action of a poison, are attended by the deposition in the cell-bodies of granules of albuminous matter and globules of fat. At the same time there is a change in the nutrition of the cells, and they are often broken and disintegrated. Under these conditions there may be a considerable congestion of the vessels and an exudate of serum.

Very large doses of such poisons cause the death of the cells of the viscera, a death which may take the form of coagulation-necrosis or of disintegration and breaking down of the cells. With these changes there will often be an excessive congestion of the vessels and a large exudation of serum.

In many examples of acute exudative inflammation the only results of the inflammation are the inflammatory products and the death or degeneration of the tissues. Such an inflammation is regularly a transitory process; if it is not so severe as to cause death, it runs a limited course, the congestion subsides, the escape of the elements of the blood from the vessels ceases, and the tissues return to their natural condition. It may, however, happen that in an exudative inflammation there will be, from the very first, not only a production of serum, fibrin, and pus, but also a growth of new tissue. This new tissue, when once produced, is permanent and remains during the rest of the patient's life. Not only is this the case, but such an inflammation, instead of running a short and limited course, is apt to continue for months and years, with the continued production of more new tissue. The new tissue seems to originate in the connective tissue of the inflamed part. It is composed at first largely of cells, with but little basement substance; later it resembles more closely ordinary connective tissue. Such an inflammation may be called "productive" or "diffuse" inflammation.

The three morbid conditions just described are the morbid conditions which affect the kidneys in acute Bright's disease. All the cases of this disease are examples of an acute exudative inflammation, or of an acute degeneration, or of an acute or subacute diffuse inflammation.

We divide acute Bright's disease, therefore, into three classes and describe:

Acute Exudative Nephritis; Acute Degeneration of the kidney; Acute Diffuse Nephritis.

To these Delafield subsequently added acute congestion.

Chronic Bright's Disease.—The chronic forms of Bright's disease are of much more frequent occurrence than are the acute forms. The cases of the disease are very numerous, they present a good deal of variety in their lesions and in their symptoms, but they can all be conveniently grouped under the three heads of: Chronic Congestion of the Kidney; Chronic Degeneration of the Kidney; Chronic Diffuse Nephritis.

"Diffuse" here means with growth of new interstitial tissue. Here then are seven conditions which are defined as follows:

1. Acute Congestion, a temporary congestion of the blood vessels of the kidney which may be accompanied with exudation of serum and escape of red blood-cells. Causes: cantharides and turpentine, extirpation of one kidney, severe injuries, surgical operations especially on the genito-urinary system.

The cardinal symptom is diminished urine with albumin, casts, and blood cells in it, or complete suppression which may be fatal. Recovery is the rule.

2. Acute Degeneration of the Kidneys. An acute change in the kidneys, characterized by degeneration or death of the epithelial cells of the tubules to which may be added an exudation from the blood vessels. Causes: mercury, arsenic, phosphorus, poisons of infectious diseases, etc. The lesion varies according to the quantity and violence of the poison.

"The changes in the renal epithelial cells are: a simple swelling of the cell-body, causing it to look larger and more opaque and to take on irregular shapes; an infiltration of the cell-bodies with granules of albuminoid matter and fat; a death of the cells, which may take the form of coagulation necrosis or of a disintegration of the cell-bodies; a desquamation of the dead cells so that the tubes are filled with them;

a formation of hyaline masses in the cells; a growth of new cells to take the place of the dead epithelium. All these changes are most marked in the convoluted tubes. In the kidneys with extensive necrosis of the epithelium there may also be congestion of the blood-vessels and casts in the tubes.

Symptoms.—With the severe acute degeneration which follows the ingestion of large doses of arsenic, mercury, or one of the other inorganic poisons, the urine is diminished in quantity, or suppressed; it contains albumin, casts, and blood; its specific gravity is unchanged. At first the general symptoms belonging to the poison predominate, but as these subside the patients continue to live and suffer more or less severely from the degeneration of the kidney. They become feeble, pass into the typhoid state, and often die.

The acute degeneration which accompanies the infectious diseases such as scarlatina, diphtheria, typhoid fever, pneumonia, etc., is for the most part of mild type and gives no symptoms except the presence of a little albumin and a few casts in the urine. It is of importance to recognize the frequency with which this affection of the kidney occurs, the slight injury which it inflicts on the patient, and the completeness with which the kidney lesion disappears after the recovery from the primary disease. Much unnecessary anxiety is often felt by physicians because in a case of pneumonia or some other infectious disease they find albumin and casts in the urine. There are fears not only of death from the primary disease, but of the subsequent development of "Bright's disease." If the albumin and casts are due to degeneration of the kidneys, anxiety is needless. The course of the primary disease will not be changed. If the patients recover their kidneys return to their normal condition.

With yellow fever, with acute yellow atrophy of the liver, and occasionally with the other infectious diseases the degeneration is of intense type, with the death of a large part of the renal epithelium and exudation from the vessels. In such cases the urine is scanty or suppressed. It contains albumin, casts, and blood. The patients are very ill, they may have convulsions, delirium, or stupor; they often die. But it is hard to tell how many of their symptoms are due to the complicating kidney lesion.

3. *Acute Exudative Nephritis*.—"An acute inflammation of the kidneys characterized by congestion, exudation of the blood plasma, emigration of white blood cells, diapedesis of red cells, to which may be added changes in the renal epithelium and glomeruli." Causes: primary or secondary to any infectious disease, especially scarlet fever; occurs also with pregnancy.

"In a nephritis of this type we should expect that the inflammatory products, the serum, white and red blood-cells, and coagulable matter from the blood-plasma, would collect in the Malpighian bodies and tubes, or infiltrate the stroma between the tubes; and that of the inflammatory products in the tubes and Malpighian bodies a part would be discharged with the urine and a part be found in the kidney after death. We should also expect that the quantity of inflammatory products would be in proportion to the severity of the inflammation, and that an excessive number of pus-cells would belong to the especially severe forms of the disease. Still further, it is evident that with the milder examples of nephritis, with but little exudation, no inflammatory products might be found in the kidney after death, all having been discharged into the urine during life. As a matter of fact, the kidneys do present just such changes. When the patient recovers the kidneys return entirely to normal.

These cases show large amounts of albumin and casts and blood, subcutaneous dropsy, increased blood pressure, gastrointestinal and cerebral symptoms, and convulsions. They may be so mild as to be overlooked. They regularly recover unless death occurs with anuria or other severe symptoms early in the disease. They do not become chronic.

There is a special form with an exudate of pus either in the tubes or in the stroma which is very fatal.

4. *Acute Productive Nephritis*.—"An acute inflammation of the kidneys, characterized by exudation from the blood vessels, a growth of new connective tissue in the stroma and changes in the epithelium and glomeruli."

"This is the most serious and important of the forms of acute nephritis, for the reason that its lesions are from the first of a permanent character. It does not follow exudative nephritis, nor is it merely a modification of it; from the very onset it is a different form of inflammation. In the kidneys of persons who have been sick only a few days the characteristic lesions are already evident."

To the lesions seen in acute exudative, two more are added: (1) a growth of new connective tissue in all, often in wedges; (2) a development of the capsule cells of the glomeruli to form "half moons" in some. The kidney never can return to normal for the stroma and glomerular changes persist. Apparent recoveries are apt to be followed years later by further kidney disease.

The onset may be acute or subacute and the course is longer than in the exudative type. The dropsy involves the serous cavities as well as the skin.

5. *Chronic Congestion*.—"A persistent overfilling of the kidney capillaries and veins with blood due to some obstruction of the circulation such as valvular disease, myocardial weakness, aortic aneurysm, pleural effusion. The glomeruli show the most constant and characteristic change, their loops being thickened and dilated; the epithelium of the tubes is flattened, or it is swollen and its individual cells separated from each other. The pyramidal veins are dilated. There is no growth of new connective tissue. There are no renal symptoms. The urine is small in amount, of high gravity and contains a little albumin and a few casts. The importance of the condition is that it may lead to a chronic nephritis."

6. *Chronic Degeneration of the Kidney*, characterized by degenerative changes in the renal epithelium caused by the same circulatory disturbances which produce chronic congestion, by chronic wasting diseases, such as phthisis and cancer, and in some cases occurring primarily without known cause. The renal epithelium is swollen and coarsely granular but there are no changes in stroma, arteries or glomeruli. The urine shows little albumin; neither dropsy, increased blood pressure nor cardiac hypertrophy occur. The importance of the condition is that it may lead to chronic nephritis. The rare primary cases are difficult to diagnose. They may be the cause of death from inanition.

7. *Chronic Nephritis*.—"A chronic inflammation of the kidney attended with a growth of new connective tissue in the stroma, permanent changes in the glomeruli, degeneration of the renal epithelium, and sometimes changes in the walls of the arteries." It has been customary to hold that in one set of these kidneys the primary and most important changes are in the renal epithelium, while in another set of kidneys the primary and important changes are in the stroma.

"In other words, that the cases of chronic nephritis can be divided into two classes, parenchymatous nephritis and interstitial nephritis. I do not think that this classification is supported by facts."

In all the forms of chronic nephritis changes are to be found in the renal epithelium, the glomeruli, and the stroma. Whether the changes in the stroma, the glomeruli, or the epithelium are the more marked makes no difference in the clinical symptoms. But the presence or absence of exudation from the renal blood-vessels does correspond to a marked difference in the symptoms. The existence of the exudation from the renal vessels is easily shown by the presence of serum albumin in the urine. In this way we readily distinguish two forms of chronic nephritis, one with exudation and one without.

The way of looking at the matter, then, is this: we find after death from chronic nephritis a great many varieties in the gross appearance of the kidneys. Some are large, some are small, some are red, some are white, etc. There is no regular correspondence between these different gross appearances of the kidneys and the clinical symptoms.

We find in these same kidneys changes in the renal epithelium, in the stroma, in the glomeruli, and in the arteries. Sometimes one, sometimes another of these elements of the kidneys is the most changed. There is no regular correspondence between the predominance of the changes in one of the kidney elements over the other and the clinical symptoms.

The easiest working scheme is to admit that in

chronic nephritis all the elements of the kidney are more or less changed, but that the cases vary as to whether there is or is not an exudation of serum from the blood-vessels. The presence or absence of such an exudation does correspond to a well-marked difference in the clinical symptoms. In the present state of our knowledge and for clinical purposes, we divide all the cases of chronic nephritis into two classes; chronic nephritis with exudation and chronic nephritis without exudation. It is admitted that it is easy to divide up these kidneys according to their anatomical changes, into a number of fairly well marked classes. But as this division does not correspond to clinical divisions it is valueless for clinical purposes.

Although it is convenient to describe two forms of chronic nephritis—one with much albuminuria and dropsy, and one with little or no albuminuria or dropsy, yet it must be remembered that these are not separate lesions of the kidneys, but varieties of the same lesion. For in all these kidneys two changes are constant—productive inflammation of the glomeruli and stroma, and degeneration of the renal epithelium. The only real difference between the kidneys is whether, besides the growth of new tissue and degeneration of renal epithelium, there is or is not an exudation of serum from the blood-vessels of the kidneys."

A considerable number of cases of chronic nephritis follow an attack of acute or subacute productive nephritis. The conditions of chronic congestion and chronic degeneration of the kidney are not infrequently followed by a true nephritis. Syphilis, chronic tuberculous inflammation of any part of the body, chronic endocarditis, and chronic suppurative inflammations are often complicated with chronic nephritis. It is very difficult to find a satisfactory cause for the primary cases. There are many of these, especially in young and middle-aged adults. The nephritis is developed in a slow, insidious way in persons whose previous health has been good, and in whom no exciting cause is discoverable.

(A) *Chronic Nephritis with Exudation.*—Symptoms: Urine reduced in acute exacerbations, increased in later stages, even up to 100 ounces a day. Specific gravity of the urine and percentage of urea gradually fall. Albumin and casts vary in amount with the activity of the inflammation, in general they correspond to the dropsy.

Secondary anemia with a peculiar pallor is a very constant feature. Dropsy is almost a constant symptom, for it forms the basis of the clinical classification. Increase of blood pressure may be present or not, and cardiac hypertrophy also is usual but not constant. Chronic uremia with alternating delirium and stupor is an ordinary mode of death. Albuminuric retinitis may occur at any stage and is of bad prognosis. Dyspnea is a nearly constant symptom but arises in various ways: hydrothorax, edema of the lungs, contraction of the vessels, failing heart. Anorexia and vomiting are very frequent. There is hardly any limit to the variations of the disease but the "most constant symptoms are anemia, dropsy and albumin in the urine."

(B) *Chronic Nephritis without Exudation.*—This form belongs more to people over 45 and is apt to be associated with chronic inflammation of other organs. The symptoms differ from those in the above type in the following ways: albumin and casts are less constant and less in amount; dropsy is usually absent and more dependent on circulatory difficulties; acute uramia, dependent on vascular contraction, is more frequent than chronic uremia. The symptoms due to complications, such as cardiac hypertrophy and valvular lesions, arteritis, and emphysema, are more frequent and more prominent.

II. VOLHARD AND FAHR'S CLASSIFICATION.—Volhard and Fahr approach the subject as follows:

Pathogenesis and Classification.—The chief difficulty in a classification of Bright's that corresponds at once to pathological and clinical observations is that there is no agreement about the pathogenesis of the various forms.

At Meran in 1905 the pathologists expressed a certain resignation in this matter and the clinicians were

even less able to lead the way to a common viewpoint. Since then the clinicians have spoken loudly, questioning the possibility and also the necessity of such a unifying comprehension, a position which evidences a similar resignation on their part.

And still it seems to us that an agreement about the pathogenesis and a consequent pathogenetic classification is possible. Such an one has gradually developed for us in our work together as pathologist and clinician and is finally to be here presented.

With the greatest esteem for biological criticism and recognition of the importance of the principle of judging aberrations of normal function by functional standards, our ultimate objective is to bring clinical symptoms into correspondence with pathological findings; not so much for the purpose of standing the test of pathological anatomy, as from the necessity of understanding the abnormal functions, that is, in the final analysis, in order to be able to refer them back to pathological processes, to cellular changes, or definite chemical products of diseased cell activity.

A functional classification must not, under the pretext that functional changes have nothing to do with the microscope, lead away from pathological anatomy. On the contrary it should lead to increasing cooperation with and dependence on Pathology, and the failure of a histological method only demands further perfecting of technique but gives no license for any but an anatomical interpretation of disordered function.

For the sake of being better understood I shall begin with the generally used, though completely useless division into parenchymatous and interstitial forms. We have found that neither of these forms represents a pathogenetic unit.

The proper clinical criteria for classification are blood pressure and kidney function. We have found with the same "parenchymatous picture" two types, one with blood pressure and one without, and among the "interstitial" high tension cases again two types, differentiated by presence or absence of failing kidney function.

1. The so-called parenchymatous, nonindurative forms. Here the blood pressure is the important classifying feature, for it has been found to correspond to an anatomical difference. In the gross "large white kidneys" are found both without and with increased blood pressure and this has led to the false conclusion that large white kidneys were all the same lesion and the blood pressure an unessential complication. When the blood pressure fails, so do the evidences of inflammation, viz., hyperemia, stasis, exudation, proliferation. In this group degeneration of the epithelium is the essential change, the stroma and blood vessel changes sinking far into the background, though when fully established they do show leucocyte infiltration as well as stroma increase. Unquestionably these inflammatory changes, because of their meagerness and their absence in fresh cases, are to be regarded as secondary and stimulated, as Weigert interprets them, by the products of cell degeneration and as a replacement fibrosis that finally reaches a large diffuse development and may lead to contraction.

If now we turn to inflammation and its primary vascular changes it is evident that these must be present in, and characterize, any true nephritis. The degeneration cases in which inflammatory changes fail can then be called nephrosis in contradistinction to the inflammatory ones.

The etiology of primary degeneration types or nephrosis cases without increased blood pressure is unknown, but it is characteristic that they cannot be referred to any of the known agents that injure the kidney.

The evidences of nephritis are blood pressure and blood in the urine, and, under the microscope, an inflammation of the glomeruli as well as the extensive epithelial degeneration, which is common to both types of large white kidney and on which extensive dropsy chiefly depends. As a rule the damage to the epithelium is an anemic degeneration, the result of the glomerulitis, the inflammation of the vessels, occlusion of the capillary loops, and stopping of the blood stream and of the oxygen supply. In some cases, however, the severity of the epithelial changes are out of all pro-

portion to the glomerulitis, both in extent and degree, and such cases we regard as mixed forms, when nephrosis and nephritis coexist, probably due to a common poison.

We believe that increased blood pressure depends (except in cases of anuria) on diffuse involvement of the kidney vessels and that dropsy, on the other hand, is induced by changes in the tubular epithelium, a constant lesion in simple nephrosis, but also a frequent complication in nephritis.

The waxy kidney has been described as a separate type of disease, but it has been noted how often it gives the clinical picture of nephrosis without cardiac hypertrophy, retinitis and uremia.

We do not believe that a typical amyloid kidney can be differentiated from nephrosis without amyloid. We therefore regard it as an unessential complication of nephrosis and regard both the epithelial and vascular changes as due to the same cause. The same conclusion holds for the contracted nephrotic kidney with and without amyloid. Amyloid changes in no way alter the symptoms. For these reasons the amyloid kidney as a separate entity is omitted from the classification.

Though increased blood pressure never occurs in nephrosis it may also fail in some forms of nephritis, viz., embolic focal nephritis, interstitial focal nephritis, and focal glomerulonephritis. The focal cases bespeak a bacterial infection, rather than a soluble toxin as the causative agent. Rise in blood pressure thus differentiates diffuse and focal nephritis and the blood pressure is to be referred to the diffuse or general involvement of the glomeruli; that is to say, of the vessels.

The differentiation of nephrosis from focal nephritis depends on large amounts of dropsy and albumin in the former and hematuria in the latter.

The terms acute, subacute, and chronic are not good for classification, but useful in denoting stages of each type. They indicate prognosis, stage, duration, onset, and course. Chronic usually means not curable, but this does not apply strictly to nephrosis.

1. The "Interstitial" or Indurative Form.—The classical symptoms of these are cardiac hypertrophy and high blood pressure. These we have divided by a study of renal function into a benign group with good function and a serious group with failing function.

(a) The group with good function includes the "red atrophic" or "red granular" kidney, and also its developmental stages, in which there is no contraction and often no granulation. New connective tissue may or may not be present, varying numbers of glomeruli are diseased, but all these cases of the benign group have two common features: (1) elastic proliferation of the intima of the kidney vessels. (2) Absence of degeneration of the uninvolved parenchyma and of any considerable inflammatory reaction. The patient behaves as a simple cardiac with arterial symptoms referable to kidney, heart, brain, or peripheral vessels, depending on the location of the lesions.

(b) The second differs from the first in exhibiting renal insufficiency and shows a secondary contracted kidney, the scarring stage of an inflammatory process with extensive parenchymal changes. In early stages the contraction may be slight or lacking. "Secondary" may be applied also to contraction after nephrosis, and after diffuse and focal glomerulonephritis.

These cases show very high blood pressure and cardiac symptoms combined with renal insufficiency and, histologically, marked arteritis of the small and smallest vessels with an inflammatory glomerular change: a combination form. The smallest vessels are more often involved in this form than in the simple sclerosis. This may be the predisposing cause of the parenchymal changes. In any case in the combination forms the vascular change is primary and older; the inflammatory or parenchymal more recent and secondary. A group of "contracted kidney" is impracticable because contraction cannot be diagnosed in life. The disturbance of renal function is the important feature, and this depends on destruction of parenchymal secretory tissue quite independent of the degree of contraction, so we prefer to call these cases of hypostenuria and failing renal function "End stages."

We do not base our classification upon etiology because in part of the cases it is unknown and in another set it is the same for all.

The pathological significance of four cardinal symptoms in these conditions is then as follows:

(1) Dropsy depends on degeneration of the epithelium of the convoluted tubules.

(2) Hematuria depends on inflammation of the kidney especially expressed in glomerular and interstitial lesions.

(3) A large amount of urine of low and constant gravity (hypostenuria) indicates a failure of renal function and an extensive destruction of secretory renal tissue.

(4) High blood pressure and cardiac hypertrophy depend on arteriosclerosis of the renal vessels (in so far as they depend on the kidney at all).

Two tabulated classifications are given in the work, one by Fahr in the pathological portion, the second by Volhard in the clinical section. That of Velhard is here given, slightly amplified in detail to include all that appears in Fahr's scheme.

PATHOGENIC CLASSIFICATION OF BRIGHT'S DISEASE.

A. Degenerations, affecting principally the tubular epithelium. Nephrosis.

1. Genuine simple nephrosis of unknown origin.

Four stages, viz., (a) cloudy swelling, (b) epithelial degeneration, (c) growth of interstitial tissue (d) nephrotic contracted kidney with failing function, but no increase of blood pressure.

2. Secondary simple nephrosis of known origin. Above stages not so distinctly developed.

3. Characteristic nephrosis; presenting, in addition to common features, lesions peculiar to a special poison.

4. Necrotizing nephrosis, with death of epithelium. (A lesion may be at once "characteristic" and "necrotizing," as the bichloride kidney, and thus belong at once to 3 and 4.)

5. Complicated nephrosis; the amyloid kidney. Three stages correspond to last three of simple nephrosis.

B. Inflammations, affecting chiefly glomeruli and stroma. Nephritis.

1. Diffuse glomerulonephritis with increased blood pressure. ("Diffuse" here means that all the glomeruli are inflamed.) Three stages, viz., acute, chronic, and end stage with failing renal function.

2. Focal nephritis without increased blood pressure. (a) Focal glomerulonephritis, acute and chronic stages, (b) septic interstitial focal nephritis, (c) embolic focal nephritis.

3. Mixed forms of nephritis and nephrosis.

C. Arteriosclerosis—affecting primarily the renal vessels—always associated with hypertension.

1. Simple sclerosis.

2. Combination form, sclerosis plus nephritis, true contracting kidney with rapidly fatal course.

A. Nephrosis comprises all purely degenerative lesions and those whose inflammatory nature is not entirely beyond question. They are caused by poisons, either bacterial, mineral, or metabolic, and sometimes they arise without known cause and are then termed genuine.

1. Genuine nephrosis occurs in four stages.

(a) Cloudy swelling, in which the cells are enlarged and the Altmann granules are irregular in disposition and various in size. Glomeruli and stroma normal. This causes no symptoms except a trace of albumin and a few casts. It is very common and occurs as an incident in many infections.

(b) Epithelial degeneration, in which hyaline droplets and fat collect in the cells and some nuclei disappear. Glomeruli and stroma normal. This occurs under the same circumstances as cloudy swelling, causes no more symptoms, and like it, vanishes completely as the primary infection subsides. It also may produce the fully developed clinical picture of nephrosis with dropsy and much albumin in the urine, which occurs either in early amyloid kidney, in genuine nephrosis, or in the large white kidney with hypertension which we call the "mixed form."

(c) Inflammatory reaction in vasculo-connective tissue, in addition to epithelial degeneration. There is a definite growth of new interstitial tissue, some desquamation of the epithelium of the convoluted tubes, some dilatation of the tubes, and rarely some regenerating epithelium. Glomeruli are normal. (These observations are based on only two cases, all that the authors have seen at autopsy.) In these the complete clinical picture of nephrosis occurs. Marked oedema of skin and serous cavities due to permeability of the vessel walls is the most striking symptom. The transudates are milky and poor in albumin. Urine of very high gravity, small in amount, and containing large amounts of albumin and many casts and fatty cells, but seldom any red cells. Blood shows no anemia in spite of the pale skin, the serum is milky, like the transudates. Rest nitrogen is never much increased, values of 80 mg. are infrequent, and 100 mg. was only seen shortly before death or with anuria incidental to a complication.

True uremia due to failure of the excretory renal function never occurs.

Anorexia and watery diarrhea are regular symptoms. The absence of increased blood pressure and of cardiac hypertrophy are characteristic. "We only saw them when renal arteriosclerosis was present in addition." Eye ground changes are never observed.

(d) Cicatrization with destruction of both tubes and glomeruli by the contraction of the inflammatory interstitial tissue. A few glomeruli primarily inflamed. Tubal epithelium degenerated and sometimes regenerating. (This description based on one autopsy in a man dying of phthisis.) With this lesion there is polyuria and loss of urinary concentrating power, but no rest nitrogen retention and no increased blood pressure, cardiac hypertrophy, retinitis, or uremia.

The course of nephrosis is slow and discouraging: first a period of very marked general edema, then one when the edema is confined to the serous cavities, then a period with albuminuria without edema, haematuria, or increase of blood pressure, and finally, unless they get well before, a final stage of hyposthenuria without increase of rest nitrogen or hypertension.

2. Secondary simple nephrosis with known cause, essentially similar to 1, but stages are less distinct both as to lesions and symptoms.

3. Characteristic nephrosis, in which some special added feature occurs with some particular causative agent, thus lime deposit and regenerating epithelium in bichloride kidneys or glycogen deposits in diabetes.

4. Necrotizing nephrosis. The epithelium of the convoluted tubes is extensively necrotic, the glomeruli are normal. Bichloride given as an example.

5. Complicated nephrosis. The amyloid kidney. The authors consider this lesion nothing more than an ordinary nephrosis of known cause, in which waxy deposits occur. The amyloid, unless in large amounts, produces no modifications in the symptoms. This nephrosis may show simple epithelial degeneration or an interstitial growth of new tissue in addition, which latter may pass on to a condition of cicatricial contraction. The symptoms are those of simple nephrosis.

B. Inflammations. Nephritis, "in sharp contrast to nephrosis. The damaging poison in nephritis produces, from the beginning of the process, strictly inflammatory changes in the glomeruli and in the interstitial tissue. The heart and the vessels are involved in the later stage."

1. Diffuse glomerulonephritis. ("Diffuse" here meaning that practically all the glomeruli in both kidneys are inflamed, while Delafield uses the same adjective in quite another sense, namely, to

mean that the stroma is involved in the inflammatory process.)

This is caused by streptococci, pneumococci, and by tuberculous. It is especially apt to follow angina.

(a) Acute stage.

The glomerular lesion dominates the picture and establishes the diagnosis. This consists in a multiplication of the glomerular cells and an elongation and dilatation of the vascular loops. The increase of cells chiefly concerns those within the loops, polynuclears and endothelium, but a swelling, increase, and degeneration of the tuft epithelium occurs also. An exudate of red, white, and epithelial cells and of albumin appears within the glomerular cavity. There is little blood in the capillary loops.

Degenerative changes in the epithelium of the convoluted tubes as described in nephrosis is the rule, but varies greatly in amount. Casts, red blood cells, and coagulated albumin occur in the tubes.

There are a few small round cell infiltrations in the interstitial tissue. This condition often returns entirely to normal.

(b) Chronic stage shows more advanced glomerular and epithelial lesions and, especially, increased inflammatory reaction in the interstitial tissue.

The glomerular lesion may be that of the acute stage, intracapillary, or there may be in addition an extensive ingrowth of the capsular epithelium which compresses the tuft; "extra capillary" or "half moon form." The latter belongs to the severest cases.

(c) End stage—with profound alteration of kidney architecture through production and contraction of interstitial tissue: many tubes and glomeruli damaged beyond the possibility of functioning, others showing a compensatory dilatation and hypertrophy.

Clinically hypertension typifies the condition, though hypertension also occurs with arteriosclerosis, and with the anuria of bichloride kidneys. It is absent if the inflammation is focal instead of diffuse, in very mild cases, and in high fever and profound general weakness. Edema is very usual, but not constant; when excessive it indicates a degeneration of the tubal epithelium. Cardiac hypertrophy is the rule. Presence of blood in the urine is the surest sign of nephritis. Albumin and casts are nearly constant. Renal function and rest nitrogen are normal in the acute and chronic stages, but the end stage is marked by progressive renal failure. Such failure can supervene early, especially with the "extra capillary" lesion. Eye ground changes belong to the end stage.

Many cases recover after the acute stage, some go on into the chronic often with few symptoms, and most of these sooner or later come to a failure of renal function and the end stage which results in fatal uremia, unless death from some intercurrent condition, especially heart failure, anticipates it.

2. Focal nephritis, in which the lesion is not diffuse, but developed in foci, or patches, the intervening renal tissue remaining normal.

(a) Focal glomerulonephritis. Same lesion as diffuse, but not so extensively developed. Clinically evidenced by hematuria without increased blood pressure, dropsy, or increased rest nitrogen. Not a fatal condition, so this lesion is seldom seen. Probable that it can develop into a diffuse lesion with resulting changes in symptoms.

(b) Septic interstitial focal nephritis. The lesion consists of foci of round, plasma, and a few pus cells in the stroma, without glomerular or other changes. This gives no symptoms, even albumin is absent from the urine, or only occurs in traces. It forms part of a

general sepsis; renal symptoms only become prominent if anuria supervenes.

- (c) Embolic focal nephritis. The ordinary septic emboli that occur with an infectious endocarditis.

C. Sclerosis—primary lesions of the renal arterioles.

1. Simple sclerosis. A new growth of elastic lamellae in the intima, hypertrophy of the muscle coat, degeneration of the new elastic tissue, fatty degeneration, atrophy and replacement fibrosis in the muscle coat.

The cause is unknown, but it belongs to adults over fifty. Increased blood pressure averaging 200, and cardiac hypertrophy without hematuria, with little or no albumin, without any increase of rest nitrogen, and without neuroretinitis, make up the clinical picture. Arteriosclerosis of the heart and of the brain often complicate it.

This disease often causes no symptoms for long periods, and runs a chronic course, but always with the possibility of fatal arterial attacks.

2. Combination form. A sclerosis like the last but always involving the smallest renal arterioles, which is subsequently complicated by progressive inflammation of the glomeruli and interstitial tissue, finally leading to a destruction of secretory tissue so extensive as to cause failure of renal function.

As soon as this complicating inflammation develops the chronic course changes to a rapidly unfavorable one, albuminuria appears, the blood pressure rises, averaging 240, the heart becomes enormously enlarged, and tends to fail, arterial symptoms become aggravated, loss of flesh and strength is rapid, secondary anemia and cerebral symptoms appear, rest nitrogen accumulates and fatal uremia is the necessary conclusion. Neuroretinitis is especially typical of the condition and often appears before any other symptom.

III. COMPARISON OF THE TWO CLASSIFICATIONS.—

Both these classifications constitute a determined attempt to interpret renal symptoms in terms of renal lesions, which is the basis of their strength.

Both differentiate between degenerative changes in the tubular epithelium and inflammation of the organs as a whole.

Both consider the ubiquitous division of kidney cases into parenchymatous and interstitial as useless, invalid and misleading.

Both Delafield and Fahr describe almost precisely the same microscopic lesions of glomeruli, tubes, stroma and blood vessels, although their comprehensions of the pathogenesis and clinical significance of the varying combinations of these individual lesions differ, at times widely.

Volhard and Fahr have the advantage of more various and refined histological methods and of all the recent methods of studying renal function, hypertension, etc., an advantage which they improve to capacity. It is a little surprising that, in the matter of illustration, while their colored plates are excellent, they cannot compare with the microphotographs of Delafield's original work.

Delafield describes acute and chronic congestion as distinct pathological and clinical entities. Acute causes diminished urine or anuria, which leads him to the belief that diminished and suppressed urine in acute nephritis and in exacerbations of chronic are due to the concomitant acute congestion. Chronic congestion causes a definite dilatation and thickening of the glomerular loops but no changes in the stroma. It causes only minor clinical manifestations, but is important because it may be followed by a chronic nephritis, with the growth of cells in the altered glomerular loops and of new interstitial tissue.

Volhard and Fahr do not describe either of these conditions. They repeatedly describe the anuria of acute inflammation, but do not attribute it to congestion. They refer to the chronic congestion incident to cardiac difficulties, but do not describe the lesions and nowhere indicate that it may lead to a chronic nephritis. I have among Delafield's own slides excellent specimens of these glomeruli of chronic congestion, both before and after the incidence of the inflammatory cell growth, and there can be no question as to the lesions he describes.

Although in the degenerative changes the lesions described by both Delafield and Fahr are practically the same, it is here that the widest divergence in the conception of their pathological development and clinical significance occurs.

Both have seen cloudy swelling, vacuoles, and fatty deposits in the renal epithelium without glomerular changes as an incident in all sorts of infectious diseases and causing no symptoms or only a trace of albumin and a few casts in the urine.

Both have seen necrosis of the renal epithelium with mineral poisons, and Delafield has seen it in yellow fever and acute yellow atrophy as well.

Both have seen young people with dropsy, large amounts of albumin and casts, and pallor and prostration, without hypertension or cardiac hypertrophy, and found a large white kidney with extensive fatty and degenerative changes in the epithelium, new cell growth in the interstitial tissue, and little change in the glomeruli.

Both have seen the same clinical picture, but with hypertension and a big heart combined with a similar pathological picture in which Volhard and Fahr however see more glomerular changes.

Both have seen waxy kidneys, with new cell growth in the stroma and much albumin and dropsy, accompanying wasting diseases.

For Delafield, cloudy swelling, vacuoles, and fatty infiltration in the cytoplasm, failing nuclear stain, desquamation and wholesale necrosis of the cells are simply steps in one process whose severity depends on the degree of the poison. Regenerating epithelium he saw and described in bichloride. Necrosis he saw after mercury, arsenic, phosphorus, yellow fever, and acute yellow atrophy of the liver. In many cases, especially the more pronounced, a minor inflammatory reaction occurs in conjunction, but no glomerular or interstitial changes.

Clinically he found only traces of albumin and granular casts, except in the necrotic forms, and in none of them did he ever see dropsy.

For Delafield a kidney with definite new cell growth in the stroma, in addition to changes in tubes and glomeruli, without or with cardiac hypertrophy and hypertension, is a case of chronic nephritis.

Waxy kidneys, also, according to Delafield's conception just given, are a special type of chronic nephritis.

Volhard and Fahr have seen cloudy swelling, hyaline deposits, and fatty deposits and some loss of nuclei, with traces of albumin, a few casts, and no dropsy, as an incident in many infections. They assume, however, that hyalin droplets and fatty deposits and fading nuclei, with no other changes—in other words, a pure degenerative lesion—can

cause large amounts of albumin in the urine and extensive dropsy, but they have never seen such a case at autopsy, at least they do not report any.

It is just here that Delafield has the advantage of them, for he has seen many cases of pure chronic degeneration at autopsy. Some incident to heart disease and stasis, some to chronic wasting diseases, and some arising primarily and constituting the only important lesion at autopsy. In no such case did he see more than a trace of albumin or any renal dropsy.

Volhard and Fahr, perhaps because they have not seen such autopsies, consider kidneys with much degenerated epithelium, a growth of new interstitial tissue, and absence of hypertension and of cardiac hypertrophy the normal outcome or later stages of cloudy swelling, cytoplasmic degeneration and fading nuclei. They have only seen three such at autopsy.

Although, as above stated, they have seen these degeneration changes with acute infections repeatedly without dropsy (see page 12), they yet regard the epithelial degeneration as the cause of pronounced albuminuria and of dropsy, not only in all this group which they call nephrosis, but also when associated with definite inflammation, glomerular and interstitial lesions, and hypertension.

They further consider necrosis of the epithelium an aberrant form of degeneration instead of the natural final stage of the degenerative process, even in spite of having seen transitional lesions with early and partial necrosis.

In waxy kidneys they regard the epithelial degeneration as the one important change and the cause of albuminuria and dropsy, and regard the amyloid deposits, interstitial, and glomerular changes as comparatively negligible. The occasional hypertension they refer to complicating renal arteriosclerosis.

I have tried to state their view fairly, the more because I disagree with it. It appears unsound, for the reasons: (1) its autopsy support is altogether inadequate; (2) renal dropsy has not been shown to occur with epithelial degeneration alone; and (3) in other organs, such as the nose, colon, etc., large exudates of albuminous fluid have not been shown to be primarily dependent on epithelial degeneration.

Turning now to the inflammations, we find similar fundamental conceptions of the process; namely, that the blood vessels are always concerned, that exudation of blood elements is an essential part of it, and that new cell growth in the stroma may or may not occur. Practically, however, the two views present differences.

Volhard and Fahr regard glomerular inflammation as the pivotal fact in all nephritis, except a rare septic interstitial form and the cases with septic emboli that accompany infectious endocarditis. The two main questions for them are: (1) whether all the glomeruli or only part of them are diseased, and (2) whether the inflammation is of the intra- or extracapillary type. Only in diffuse glomerulonephritis, *i. e.*, where all the glomeruli suffer are renal symptoms developed to any extent. The extracapillary form is much the severer, but only appears late in the course of cases which have not been properly treated in the acute stages. In

their opinion no acute case of nephritis should become chronic if properly treated.

Delafield, on the contrary, draws a sharp distinction between two types of acute nephritis. In one, acute exudative nephritis, the inflammatory process consists of exudation of the elements of the blood, with or without glomerular changes and degeneration of epithelium. Recovery occurs in almost all, and with recovery the kidney returns entirely to normal. In the other, acute productive nephritis, in addition to the above changes, there is a growth of interstitial tissue from the outset, and the glomeruli are invariably altered. This lesion always leaves permanent damage. Delafield shows a microphotograph of such a kidney on the sixth day after acute onset of symptoms. These cases also often show the "extracapillary" type of glomerular inflammation from the outset, a fact which Volhard and Fahr fail to recognize. Altogether, Delafield's comprehension of acute nephritis is the more adequate and corresponds better to clinical experience.

It is interesting to note, in passing, that both observers recognize a rare acute septic form with a large exudate of pus in the interstitial tissue and unassociated with much albumin in the urine. Delafield also saw cases of the same kind but with the pus in the tubules, so he called the condition acute exudative nephritis with pus cells, while Volhard and Fahr, having seen only the interstitial type, call it septic interstitial focal nephritis.

When it comes to chronic nephritis, Delafield recognized the various lesions and also insisted on the fact that in every chronic case showing renal symptoms, such as dyspnoea, dropsy, hypertension and hypertrophy, uraemia, and so on, the changes in the secretory tissues were invariably accompanied by changes in the stroma, so that, for him, the absence of such stroma changes meant that the case was not one of chronic nephritis. Delafield, however, frankly confesses his inability to cope successfully with the classification of chronic nephritis.

It is this group, especially, that Volhard and Fahr attempt to analyze and subdivide. In the first place, they take out the cases with dropsy and albumin, but without hypertension, and call them nephrosis, a move that has already been discussed. Next they divide chronic nephritis into a chronic stage with good renal function and an end stage where this fails, unquestionably a valid and helpful distinction. Also the division of uremic symptoms into those due to failure of renal excretion (true uremia), to edema of the brain (elamptic uremia), and to spasm of the cerebral vessels (pseudo-uremia) is most enlightening and suggestive. In fact, the study of renal function as a whole with the results of various functional tests is a most excellent and valuable contribution and would, in itself, be enough to entitle the work to the highest consideration.

Finally they separate all the cases whose primary lesion is in the arterial walls, calling them sclerosis, and divide them, as above indicated, into simple forms, and those followed by a secondary inflammatory change in the secretory tissue not directly compromised by the sclerotic process. All the scleroses, except the earliest, having a stroma change, fall in Delafield's chronic nephritis group.

In support of their views concerning sclerosis, Volhard and Fahr cite numerous cases with autopsies and, to my mind, present a very strong and convincing argument. If their conception of renal sclerosis proves correct, as it promises, it is destined to greatly amplify our knowledge of a dark and difficult subject.

There is a joint in the armor, however, which, though it does not invalidate the sclerosis group, confuses their presentation of nephritis, and to this I wish to draw attention.

Just as they look at degeneration of epithelium as the cause of renal dropsy and albuminuria, so they regard sclerosis as the cause of renal hypertension. They state, however that hypertension is an obligatory and distinguishing feature of diffuse glomerulonephritis, but is absent in focal glomerulonephritis, in fact in focal nephritis of all types. They believe this invariable hypertension in diffuse glomerulonephritis to be due to the lesions in the glomerular loops, but these are not at all the same as those which they describe as occurring in the arterioles in sclerosis.

They expressly state elsewhere that mere occlusion of vessels, such as occurs in glomeruli, is not a cause of hypertension, and they do not claim that in sclerosis all the vessels are affected before hypertension arises. Sclerosis, in fact, is a typical "focal" lesion, according to their own description, and the surest cause of hypertension, yet when only part of the glomeruli are diseased a diagnostic distinction is absence of hypertension. On the other hand, they do not regard hypertension in glomerulonephritis as regularly dependent on sclerosis, for then they would have to demonstrate or assume the existence of sclerosis in all diffuse, and its absence in all focal glomerular lesions, which they nowhere attempt.
